I think here the author acknowledges that the patient's mind must be diverted from the injured part, and I am sure that the remedial measures adopted in the article do not do that. Even in the competitive games the patient's mind is still fixed on how much the injured limb or damaged joint will stand. The same is true of physiotherapy: the patient's whole attention is fixed on the injured part, whereas in occupational therapy his mind is guided away from his injuries by means of pleasurable occupations, constructive and absorbing, by no means boring or seemingly unnecessary, but actually with an additional educational value. And yet the very movements so necessary for rehabilitation are brought into repeated play in a way in which the patient is hardly conscious of the fact that they are being so used. In this way the patient reaches the same stage of rehabilitation, but reaches it by more pleasant pathways, and I am sure that by the addition of occupational therapy, properly employed by a qualified occupational therapist, to the means at the writer's disposal, he will be able to do away with the "notice" illustrated and quoted in full in the caption of Fig. 1.—I am, etc.,

ANDREW SHEPHERD.

Medical Superintendent of an E.M.S. Hospital
with a Special Department for Orthopaedic Cases.

Sept. 27.

Treatment of Haemorrhagic Disease of the Newborn

SIR,—The article on the treatment of haemorrhagic disease of the newborn (September 27, p. 433) is interesting, and the subject is one concerning which I should like to hear more.

It has not been my lot to deal with many of these cases, but chance observation led me to the application of a simple method which has been successful in my past five cases. Very early I came to the belief that simple transfusion of blood was by no means a certain method of therapy. Some factor other than mere quantity of fresh blood was required. I turned to the injection of blood into the child's back, and this happening followed. In my first two cases I injected the mother's blood, but with no effect. The father was not available in the first case, but his brother was found and his blood injected. Recovery followed immediately. In the second case the father's blood was also got, with the same pleasant result. Since then I have had three cases, in each of which I have used the father's blood, and each one has recovered. In the two most recent ones, because they were severe, blood running from mouth and rectum, I have also used hemoplastin (P. D. and Co.).

The method I use is to take 2 c.c. of 4% citrate to 20 c.c. of the father's blood and inject this subcutaneously and intramuscularly from the shoulders to the buttocks of the child. I have seen no bad effects either locally or generally from so doing. At the same time I now give 2 c.c. hemoplastin intramuscularly

into the thigh, and repeat this in twelve hours. Likewise I give from one to two drops of cod-liver-oil in each of frequent small feeds.

I quote this method, not to detract from the value of vitamin K treatment, but merely to record a method that appears in a small number of cases to be giving consistent good results. I should very much appreciate the criticism of those with a much wider experience of the treatment of these cases than I possess. I intend to replace hemoplastin by vitamin K, but should I omit the father's blood?—I am, etc.,

Dundee, Sept. 29.

JOHN J. ROBB.

Treatment of Impetigo

SIR,—I have followed with some interest recently the correspondence on the subject of the treatment of impetigo and scabies. During the last year I have been more than usually intimate with these two diseases, for I have been in charge of a reception station receiving such cases from at least a dozen different units spread about over an area of 400 square miles. Owing to the excellent sanitary and ablution arrangements (the building was erected to a pre-war reception station design) the treatment of the scabies patients, and the exceptionally satisfactory results obtained, cannot be fairly compared with what is possible in less well-equipped premises. Therefore I will confine these notes to the treatment of impetigo, for this can be carried out similarly in any normally equipped treatment centre.

The treatment, of course, varies with the widely different states of the patients on admission. It is noteworthy that very little attention has been paid to this polymorphism in the correspondence so far published. Roughly the impetigo cases may be grouped for treatment purposes as follows:

1. *Weeping Type*.—Large sero-rhœic areas, with perhaps a few isolated patches of scales, occurring on the neck, under the chin, on the face and ears (rarely on scalp and forehead), and usually associated with more or less thickening of the underlying corium with "bloated" appearance due to subacute inflammation.

2. *Encrusted Type*.—Dry, scaly, discrete, and itchy; chiefly on face, but, depending on severity, may extend on to the forehead, scalp, ears, and neck.

3. *Pustular*.—The secondarily infected type. Staphylococcal pustulation (Bockhart's impetigo) usually associated with dry encrusted type, and common after inefficient treatment; face, neck, and ears; often very resistant.

4. *Infiltrating Type*.—Corium infected: "ecthyma"; small areas usually on forehead or temporal regions, where burrowing infection has reached and penetrated the corium; often result of failure to receive early treatment, or of inadequate treatment of "encrusted" type.

5. *Fissured Type*.—Streptococcal fissures especially occurring at angles of the mouth ("perlèche") and behind and below auricles.

After much experimenting the principles I adopted were these: (a) First render the area entirely dry. (b) Remove crusts and scales only if this is possible without damaging the underlying epidermis. (c) Keep scalp clean by regular use of spirit soap. (d) Use suitable ointment, which must be massaged well into the affected areas with the finger-tips. (e) Use face-mask at night to prevent spread and contamination of healthy areas from pillow and fingers during sleep.

1. The weeping type needs to be rendered dry. I apply boric acid powder on lint directly to the sero-rhœic areas. If the powder is used freely enough there will be no adherence of the lint. These cases often show profuse subepidermal oedema, and the spread of infection reacts very favourably to M and B 696 2 grammes stat. and 1 gramme t.d.s. thereafter for two days. In about three days the areas are usually dry, the oedema has subsided, and the "creaking leather" feeling which the patient first noticed has disappeared. When hard crusts have formed and there is no further exudation I apply ung. hyd. nit. fort. night and morning, without removing the crusts, for two days. On the next day a compress of lint wrung out of hot 2% boric acid solution is applied to the whole crust-covered area, and repeated at intervals of fifteen minutes for one hour. The crusts dissolve away easily and a clean surface is left. An ointment ("two-in-one") made up of equal parts ung. hyd. nit. fort. and ung. zinci is then applied and well massaged into the skin for about ten minutes with the finger-tips by the patient himself under super-

vision. Thereafter this ointment is applied twice daily, and before the morning application the patient washes his hair, scalp, ears, face, and neck with spirit soap. After the evening application a face-mask is fitted (made of lint to cover the whole affected area). This routine is continued for three or four days, by which time the disease has usually disappeared. Occasionally, in very severe cases, the boric compresses have to be repeated about three days after the first application. The average time to cure these cases is eight to fourteen days.

2. The encrusted type (the average impetigo contagiosa of the textbooks) is already at the dry stage. The hair, scalp, ears, face, and neck are first washed with spirit soap and afterwards the "two-in-one" ointment is applied. This ointment is repeated at night as before. Most of the crusts are soaked off in the first wash with spirit soap, the remainder succumb to the second; on no account are any crusts "picked off." The complete routine is repeated daily and the patient is usually ready for discharge in seven to ten days.

3. In the pustular type the whole pustular area is first treated with the boric compress technique. Thereafter the "two-in-one" ointment is used as before (daily washing with spirit soap before the morning application). Usually one series of the boric compresses (over one hour) is sufficient; occasionally a second is required two or three days later. These cases are often resistant. They take about ten to fourteen days to clear.

4. The infiltrating type yields to hot boric compresses followed by application of tinct. benz. co. twice a day. The scabs must not be picked or scratched off, or the resulting scarring will be very unsightly, and also the infection will be encouraged to penetrate deeper.

5. The fissured type is often very resistant but decidedly less contagious than the other types. The fissures at the angles of the mouth usually yield to application of tinct. benz. co. and small strips of zinc plaster (about 1/4 inch wide and 3/4 inch long) placed vertically at the angles of the mouth to prevent stretching of the healing edges. The same applies to the ears.

It will be noticed that no mention has been made of shaving the head. The head is seldom affected initially, but becomes infected later on if treatment is not vigorous enough or if the patient twists a lot on his pillow at night without a mask over his face. I consider that it should never be necessary to shave the scalp. Occasionally it may become necessary to cut the hair moderately short (little more than the soldier's ordinary crop) for about 1 1/2 inches above the ears and round the back of the neck. I have never yet found it necessary to shave the head. Spread to the scalp is prevented by the frequent washing with spirit soap, and the few isolated patches that may occur can be adequately dealt with, after the crusts have been softened and removed in the usual way, by the "two-in-one" ointment. The very resistant patches can be saturated by painting with 5% silver nitrate solution in meth. I find it a great incentive to conscientious self-treatment by the patient to tell him that if the disease spreads to his scalp it may be necessary to have his hair shaved away; this usually results in redoubled efforts to limit the course of the complaint. I make, too, a particular point of the ritual of washing with spirit soap. It is important that the hair shall be free from scurf and any form of irritation, as this is a potent source of infection through scratching fingers. Also it is important to see that the washing is done in order from the least affected to the most affected parts: not all areas at the same time, as there is then greater risk of carrying infection. Also the spirit soap stimulates keratosis, which hastens the desquamation of diseased cells.

The average time taken to cure all cases is in the neighbourhood of ten to fourteen days. Only very rare cases will take longer, and then only because the treatment is not vigorous enough, not conscientiously enough supervised, or because the patient is purposely retarding his progress (I had one such patient who was found to be removing the ointment as soon as it was applied, dabbed himself freely with a proprietary poison with a prodigious name, and complained that the irritation of his face was so intense that he could not bear to continue treatment; he wasted many valuable days having soothing lotions and ointments in consequence). I have heard of cases taking fifty and sixty days to cure—one champion brand of streptococci sustained a combined attack (so I am led to believe from the notes) for 108 days. Such cases have not come my way. I have heard of cases of the weeping type treated over a long period by x rays at weekly

intervals: their improvement coincided with the intervals; others had been painted to resemble Early Britons by orderlies with artistic and possibly humorous tendencies; a few were part of a generalized sensitization dermatitis and were probably not impetiginous at all.

In conclusion it must be said that it is imperative that the nursing is of a high order. One must be sure that injunctions given to nursing orderlies are carried out to the letter. I was ably and faithfully assisted by a very conscientious team of orderlies, to whose efforts I attribute in very large part the excellent results obtained.—I am, etc.,

SEPT. 28.

JOHN W. W. JAY,
Captain R.A.M.C.

Technique of Relaxation

SIR.—As a psychotherapist, I agree more than heartily with Dr. W. Numan's objection (September 20, p. 428) to "the airiness of the use, abuse, and ill use of the word 'relaxation' in the literature of psychotherapy." As he points out, telling a patient to relax is a most efficient way of making him self-conscious and tense. Direct suggestion is rarely, if ever, as effective as indirect implicit suggestion—certainly not so in inducing relaxation of mind or body.

A few practical pointers from long experience may help Dr. Numan and others who want concrete advice. Much of the G.P.'s work is now concerned with "shell-shocked" men discharged from the Services; blitz-shocked and war-harassed and neurotic civilians generally. And relaxation induced by suggestion until it becomes a conditioned habit is about the simplest and most generally useful technique of minor psychotherapy for the G.P. (see Schultz's *Autogene Training*, Jacobsen, etc.).

Never use the word "relax"; suggestion should be implicit, not explicit.

Optimum conditions are: the patient lying on a couch, but an ordinary easy surgery chair is adequate and, better still, an old-fashioned straight-back with high-elbowed arms; a quiet room, and a natural chatty manner and voice on the part of the doctor; eschew the stage hypnotic voice or the monotonous repetitive sing-song that so many beginners affect—such hocus-pocus irritates, antagonizes, and arouses the suspicions of intelligent patients and confuses the dull ones. Walk about the room, do odd jobs, talk about other things, and even turn your back on him until he settles down. He will then not feel that he is being "influenced" or hypnotized, and any possible fear or distrust is disarmed; and don't be unctuous or over-persuasive.

My own technique varies but is often like this. At first let him sprawl in any position he finds comfortable. Then point out that every joint and limb has an optimum position which loosens the muscles most, and this varies with the patient and with his mood. Pick up his joints and adjust them in that position. The "healing hand" is a very real thing: the contact of one sympathetic human being with another has quite a magical effect which modern medicine need neither despise nor abuse. The patient's knees should be slightly everted and bent, or ankles crossed; palms loosely crossed or grasped across the abdomen or flexed by the side (some knowledge of surgical anatomy is helpful); head low on one cushion or none; or a neck pillow *à la Japonaise* and/or such pillows under the knees and small of the back, but this is an ultra-refinement hardly necessary.

Adjust, too, the neck and lumbar spine and facial muscles and tense mouth or eyes. Pick up the limbs and let them flop into the easiest position. Touch eyelids and forehead wrinkles and mouth, and very gently massage them into looseness with the balls of the fingers or thumbs. This causes the patient to look up and tires the ocular muscles into relaxation. I had a rather neutral Japanese kakemono picture on the otherwise blank wall facing him, to which his eyes would naturally stray; the design happened to be a greyish swirl of cloud or smoke which spiralled up to a point, and the rhythm and line of the picture seemed to lead the eyes irresistibly up to that point. Soon the eyes tire and tend to close. Then gently close the eyes and tell him to keep them shut if he feels like it. I have seen tense patients fall asleep, but this is no harm and means that the patient is certainly acquiring the technique.

Often I get him to cross palms on the abdomen, close his eyes and follow passively with his mind the rise and fall of the abdominal respiratory movements, without any attempt to con-

trol the breathing but merely to become increasingly aware of it. Let the emphasis be on expiration and the fall of the palms, because inspiration and breath-holding are normally conditioned and associated with effort, while expiration is associated with relaxation and sleep, and there is, I understand, a larger expiration/inspiration ratio during sleep and rest. Tirala's book on hyperpnea and its relation to breathing is worth reading. So are the empirical yoga axioms and advice: yoga (not the fake stuff so over-written, but its classics as translated by Indians) can teach Western medicine something in this respect. But words are at best a poor means of conveying and teaching muscular and kinaesthetic skills.

The technique is not difficult for doctor or patient as a rule. Many patients pick it up after a few sessions of five to twenty minutes; others can never learn it, even with major psychotherapy. Once acquired, it can be practised at odd moments, before sleeping, on a bus, or (paradoxically enough) while working efficiently and without energy-wasting fuss. A common-sensical sympathetic doctor can, by trial-and-error practice, soon acquire a technique that will actually save his time and temper with neurotic tense patients. He may have the gratification of seeing his patients "snap into" the habit of relaxing, once for all time.

Relaxation is not a radical but a symptomatic technique of psychotherapy. None the less, it may help to break the vicious circle which all neurosis at rock-bottom is; I have found it useful even with psychotics. The only danger I know of is that the patient might with faulty technique become too attached to his—or her—doctor. But then a doctor who cannot keep the patient-doctor relationship under control is surely not a good doctor.—I am, etc.,

Bridge of Earn, Perth, Sept. 29.

HENRY HARRIS, M.D., D.P.M.

Raspberry-leaf Extract

SIR.—When in general practice some years ago I had a patient whose first child was stillborn after a long labour. At 36 years she fell pregnant again. Believing that "raspberry tea" would influence her wish to have a daughter, she began at the third month to drink four pints daily of an infusion of raspberry leaves. The pulse rate rose from 86 to 106, and the blood pressure from 120/80 to 146/80 between the third and fourth months. Heart sounds were "pure"; there was no oedema; and the patient was active and well, although the rapid pulse and raised pressure persisted till term. Fourteen days past her time, after an easy labour of two hours, the baby (a girl) was born "in the caul."

Recent work on raspberry-leaf extract may explain some features of this case.—I am, etc.,

Worcester, Sept. 24.

J. GRAHAM SCOTT, M.D.

SIR.—I am extremely interested in Sir Beckwith Whitehouse's publication (September 13, p. 370), as I have so far been unable to discover in our literature any explanation of the action of raspberry leaf on the uterus.

When I was in general practice in London I heard about it through a patient, and thought it worth while trying in the case of a multipara whose previous confinements had all been very difficult. To my surprise the woman had an easy time. As it seemed a harmless enough prescription, I ordered it subsequently for a routine measure in all confinements, especially in elderly primigravidae, where I became convinced of its usefulness for avoiding perineal tears. Although the labour pains seemed less severe in themselves, the actual time was rather shorter than usual, dilatation more complete, and puerperium uneventful. For a fortnight before the calculated date the mother would take a wineglassful of the tea t.d.s., and a pint of it as soon as the pains set in.

Sir Beckwith makes me feel that I need no longer consider myself a quack for using a remedy at which some of my colleagues used to smile tolerantly when I mentioned it.—I am, etc.,

Redruth, Sept. 25.

W. E. R. MONS.

Thirst at Sea

SIR.—I wish to draw attention to the possibilities of ion exchange adsorbents in relation to the problem of obtaining a potable fluid from sea water.

The abstract (*Chem. and Ind.*, 1941, 60, 378) of a paper by R. J. Myers *et al.* claims that water treated first by a cation exchange adsorbent (phenol-aldehyde resin) and then by an anion exchange adsorbent (amine-aldehyde resin) is freed from all dissolved salts. This method is proposed as a practicable means of removing salts from various types of solution. Sea water, though not specifically mentioned, would apparently come within the scope of the claims made, and the possibility of devising equipment suitable for use in ships' boats might usefully be examined. The materials necessary for regenerating the adsorbents are, presumably strong acids and alkalis. These are inexpensive and can be carried in concentrated form.

I have found that zeolite of a type commonly used in domestic water softeners can be charged with silver ions, and that the product, shaken with 3% sodium chloride solution, yields pure water on filtration. By this device Dr. Hardy's objection (August 23, p. 286) to Sir Leonard Rogers's suggestion (August 9, p. 211) for the use of silver salts is avoided. The method would probably be impracticable at sea for various reasons connected with the high atomic weight of silver and mechanical clogging of the adsorbent by insoluble silver chloride. The idea might, however, be valuable in the laboratory as a means of removing soluble chlorides from some solutions.—I am, etc.,

Glaxo Laboratories, Greenford, Sept. 29.

W. J. HURRAN.

A Plea for Flexibility

SIR.—I write to inform your readers of an incident which illustrates a rather obvious, and surely remediable, discrepancy between the Army and the civilian medical services.

On the evening of a day filled with the usual daily struggle to keep abreast of the rapidly rising surgical waiting list, and during twelve hours of which six emergencies had already been admitted—50% being due to various navigational blunders on the part of military drivers—on this evening, at 9.30 o'clock, a telephone call from a large military hospital twenty miles away informs us that a N.A.A.F.I. worker has developed acute appendicitis. Further conversation on the telephone establishes the fact that, whereas the military hospital has plenty of beds, we have already filled the last bed even in the ophthalmic ward with a surgical case.* Yet, in spite of this, and the fact that the patient is an acute surgical emergency, he must travel those twenty miles, to be put into a made-up bed, and to be operated upon by a tired surgeon.

In contrast with the above incident, I would like to point out that, although as a general rule we do not treat military patients at this hospital, in the event of an urgent military case being brought into our emergency ward that case is treated here until he is deemed fit for removal to a military or E.M.S. hospital. Must a little latitude of arrangement such as this in the saving of human life remain impossible in the R.A.M.C.?—I am, etc.,

Sept. 22.

"R.S.O."

RADIOLOGICAL HOUSE-SURGEONS IN THE E.M.S.

Hospitals are requested to bring the following information to the notice of their medical officers as soon as possible: (1) The Ministry of Health is prepared to enrol in the Emergency Medical Service radiology house-surgeons at selected hospitals in London and the Provinces. (2) Applicants must satisfy the deans of their medical faculties or schools that they intend to take up radiology and are prepared to enter for a diploma in medical radiology at the end of their course of study. The selected hospitals will be so situated that attendance at courses of instruction will be practicable, and successful applicants will be required to undergo the appropriate course of instruction, paying the necessary fees. Applicants must have held a house appointment at a hospital for at least six months, and preference will be given to those with longer clinical experience. (3) The salary will be at the rate of £200 a year, with an additional £100 for board and lodging if the officer is required to live outside the hospital. (4) Applications should be made as soon as possible to the Director of Establishments, Ministry of Health, Caxton House, Tothill Street, S.W.1, through deans of medical faculties or schools, or through regional hospital officers or group officers (London sectors).

Obituary

Dr. CHARLES LEONARD DIGBY ROBERTS, who remained in Guernsey to tend the needs of the civilian sick during the period of German occupation, died at St. Peter Port on April 21 soon after undergoing a major operation. He was born at Exmouth in 1882 and graduated M.B., Ch.B. at Edinburgh University in 1908. From there he proceeded to London to study for the English Fellowship at St. Bartholomew's Hospital. He passed the Primary Examination but became interested in tropical medicine and went out to India, where he spent the greater part of his professional life. In due course he took the D.T.M.&H. from the London School of Tropical Diseases and became a Fellow of the Royal Society of Tropical Medicine. For some years he was medical officer of the Charteris Hospital in Kalimpong, a remote outpost, chiefly noted as being the railhead for numerous Mount Everest Expeditions. After the outbreak of the war of 1914-18 he joined the I.M.S., seeing service in the Waziristan and Persian Gulf campaigns. After the war he practised for a short time in Darjeeling, and then went to Assam, where he was medical officer to the Mariana Tea Association for many years. Finally he retired from India and began practice in Guernsey, where he had hoped to retire and enjoy a well-earned rest. He was an active member of the B.M.A., and had been honorary secretary of the Assam Branch and chairman of the Guernsey and Alderney Division. His chief hobby was the study of natural history: butterflies, birds, flowers, trees, sea shells, and freshwater shells. In India he amassed a very fine collection of butterflies, and some of his specimens proved to be new discoveries and are preserved in the Natural History Museum in South Kensington and in Bombay. His knowledge of the flora of the Channel Isles was a source of wonder to those who accompanied him on his energetic walks along the cliffs and country lanes which were so dear to him. Dr. Roberts is survived by his wife, daughter, and three sons. The sympathy of all will go out to Mrs. Roberts in her lonely exile.

Dr. MATTHEW BRUCE died on September 20 at the age of 85. After graduating M.B., C.M. of the University of Edinburgh in 1885 he practised at Ashington, Northumberland, for half a century, and held the posts of medical officer of health, public assistance medical officer, and public vaccinator for many years. A past chairman of the Morpeth Division of the B.M.A., he was a regular attendant at Annual Meetings of the Association. He was keenly interested in first aid and home nursing, and lectured on these subjects over a long period. In spite of his advanced age he was actively in charge of a first-aid post until the day of his death. In the words of the honorary secretary of the Morpeth Division, "Dr. Matthew Bruce was liked by all his colleagues, and his bearded erect figure, always on a push cycle, will be missed by all who knew him."

Dr. ROBERT HAMILTON of Harrogate died on September 24 at the age of 63 as the result of a street accident at Beverley, where he was acting as wartime deputy for a local practitioner. Dr. Hamilton was the son of a Bradford medical man, and from Bradford Grammar School went to study medicine at the University of Edinburgh, graduating M.B., Ch.B. in 1901 and proceeding M.D. in 1909. He was for some years a member of the Colonial Medical Service, and in the last war served in the R.A.M.C. with the rank of captain, afterwards practising in Oxfordshire and Somerset before his retirement to Harrogate in 1935.

I read with great regret of the death of Dr. WILLIAM ROBERTSON (writes Mr. Lewis G. Cruickshank, F.R.C.S.). I had the privilege of studying under his guidance both as an undergraduate and later during the D.P.H. course. He was a fine teacher, and his long experience in the Public Health Service made him an excellent exponent of the practical problems of the service. He was a most approachable man, and always ready to discuss with his students the problem of their future career: he was much interested in medical education, and contributed articles on the subject of postgraduate study to the *Surgeon's Hall Journal*.

His passing will be mourned by many, and the loss to the Edinburgh School of Medicine is a great one, for he was a universal favourite with students and staff alike.

The following well-known foreign medical men have died: Prof. ANTON WALDMANN, head of the sanitary department of the German War Office, as the result of a motor-car accident last autumn, aged 63; Dr. ANTON HENRICHSEN, director of the cantonal sanatorium at Herisau, best known as the author of poems and plays under the pseudonym of Otto Hinnerk; Dr. WALTER VOGT, professor of anatomy at Zurich, aged 53; and Dr. ALBERT KOCHER, a Berne surgeon, aged 45.

Medical Notes in Parliament

Lord Dawson on the Food Value of Eggs

In the House of Lords on September 30 Lord DAWSON spoke in a debate on livestock and feeding-stuffs. He laid particular emphasis on the nutritive value of the egg, and, making a comparison with milk, said that the egg was rich in protein and vitamins and, so far as vitamin C was concerned, it was even better than milk. Together, milk and eggs were a tower of nutritional strength. The egg was a very digestible and easily handled food. All authorities were agreed that without eggs and milk they could not make light food, which was especially important to workers who were beginning to get weary in mind and weak in their digestions. Although it was right that there should be a priority of eggs for children and some invalids from the point of view of preventive medicine, from the point of view of keeping the active population well and fit they could not neglect the fact that the availability of eggs played an important part. He hoped the Minister of Food would take no steps to ration eggs further, but would leave this matter to localities to be dealt with by voluntary efforts. The localities should look after the egg needs of the children and ailing citizens, and as for the rest the requirements might be met by means of a pool. The health of the workers must be maintained on a high level.

Turning to the home production of eggs, Lord Dawson said that it was going down by about 20% per hen. We could produce protein-rich foods suitable for our animals within the next two or three months. In the manufacture of acetone there was a by-product containing 50% of protein which was quite suitable for feeding poultry and animals. Castor-bean meal, now used as a fertilizer, contained an ingredient poisonous to animals, but by the ingenuity of our chemists this ingredient could be removed quite satisfactorily, leaving a protein-rich food available for animal feeding. A synthesized vegetable protein of high value had been discovered recently. It was made in part from yeast, and, he believed, was suitable for mass production. Could not large-scale production be expedited? There was even a prospect of the product being cheap, and it was going to be available for human beings. Experiments had shown that this added to the value of bread, and was extraordinarily good in the nourishment of children. Here was a product which would not only help human beings but would help in the protein feeding of animals. He urged the Minister of Food to hustle this thing on.

In conclusion, Lord Dawson appealed to the Government to postpone the reduction of poultry rations to one-sixth for a few weeks, in order to give a little more time. He said that the reduction of two-thirds which had already taken place was too great, and he did not want to see the poultry industry damaged beyond all recovery. The order which had been issued for the reduction of sales of tuberculin-tested milk by more than one-third by October 18 was a mistake, and it should be put right.

Defective Hearing in the Army

On September 30 Captain MARGESSON told Sir Francis Fremantle that he had no information about how many men and women had been invalided out of the Army or incapacitated on account of defective hearing. Sir FRANCIS FREMANTLE asked Captain Margesson to consider giving some instruction whereby men invalided out of the Army for deafness might be passed on

to the National Institute for the Deaf in order that good use might be made of these men, many of whom were extremely valuable although no longer of use for military service.

Food-poisoning on Board Ship

On September 30 Dr. MORGAN asked the Minister of Health whether, during 1938, 1939, and 1940, there were any further outbreaks of food-poisoning on board ships; whether any further outbreaks of toxic peripheral neuritis, similar to the outbreaks of Ginger or Jake paralysis in the United States, were observed and recorded; whether the fine medical work in this connexion of the medical officers of his Ministry, reported in the 1938 Annual Report of the Ministry's chief medical officer, had been repeated; whether special watch had since been kept for such outbreaks; and whether appropriate commendation had been made to the officers concerned. Mr. ERNEST BROWN said that no further outbreak of toxic polyneuritis or of other serious food-poisoning on board ship had come to his notice. He greatly appreciated Dr. Morgan's tribute to the work of his medical officers, and assured him that their watch for any serious outbreak of the kind to which he referred was a close one.

Employment of Alien Doctors

Miss RATHBONE asserted on October 2 that many general practitioners, especially in neutral and reception areas, were seriously overworked owing to the calling up of their medical colleagues, yet were debarred from securing the assistance of alien doctors in their private practices. She asked Mr. Ernest Brown to change the Regulations to permit alien doctors, accepted for the War Emergency Register, to engage in private practice under conditions thought necessary to protect British doctors, such as the limitation of the permit to the duration of the war, and, if necessary, the restriction of the permit to doctors required to work as assistants to, or partners of, British doctors. Mr. BROWN replied that under a recent Order an alien doctor who fulfilled the other necessary conditions could be placed temporarily on the *Medical Register* if he was to be employed as an assistant to a British doctor in private practice. The employment was in each case subject to the approval of the Home Secretary. A practitioner who desired to secure the services of an alien doctor could take the normal steps available to the profession, or, if in doubt, could write to the Ministry of Health.

Sir FRANCIS FREMANTLE remarked that the Central Medical War Committee would undertake these arrangements.

Medical Personnel Priority Committee

In a reply on October 2 to Sir Francis Fremantle, Mr. ERNEST BROWN said an interim report had been received from the committee presided over by the Under-Secretary of State for Dominion Affairs on the distribution of medical man-power. Action was being taken on the recommendations. These included suggestions for the establishment of regional committees to promote the maximum co-operation between civil and Service medical establishments, the continued recruitment for the time being of medical officers for the Forces at the present rate, the compilation of particulars of bed accommodation and staffing for all civil hospitals, and measures to secure greater mobility of resident medical staffs between one hospital and another.

Tuberculosis Increase: Special Inquiry

Dr. SUMMERSKILL inquired on October 2 to what cause Mr. Ernest Brown attributed the increase in tuberculosis. Mr. BROWN said he had arranged for a special inquiry, with the assistance of the Medical Research Council, into the causes of the wartime increase in tuberculosis. On June 30 last there were 1,763 persons in England and Wales who had been for upwards of ten days on local authority waiting lists for institutional treatment. Information was not available on the incidence of non-pulmonary tuberculosis in areas where pasteurized milk was unobtainable. The Ministry of Health was arranging to make available some E.M.S. beds.

Medical Examination of Miners.—On September 30 Mr. GRENFELL informed Miss Ward that to secure uniformity and speed in the urgently needed return of men to the pits under the registration scheme, the question of medical examination was determined in each case by officers of the Ministry of Labour and National Service on the facts brought to their notice at the interview.

The Services

NAVAL AWARD

Surgeon Commander George McCoull, R.N.V.R., and Acting Surgeon Commander Gerald Frederick Stavely Parker, R.N.V.R. have been awarded the Royal Naval Volunteer Reserve Officers Decoration.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL NAVY

Surgeon Lieut.-Commander CLAUD DENIS DELACOUR D LABILLIERE, R.N., who was recorded as "Missing" in the *Journal* of June 21, is now posted as "Missing, Presumed Killed" in an Admiralty Casualty List published on October 1. He was serving in H.M.S. *Fiji*, which was sunk in the operation off Crete in May last. Qualifying M.R.C.S., L.R.C.P. in 1925 he entered the Royal Navy as surgeon lieutenant in the following year, and was promoted to surgeon lieutenant-commander in 1936. He had been a member of the British Medical Association since 1931.

ROYAL ARMY MEDICAL CORPS

Prisoners of War

Temporary Major Robert Harvey.
Temporary Major Patrick David Clifford Kinmont.
Temporary Major George Albert William Neill.
Captain Arthur Geoffrey Veasey Aldridge.
War Substantive Captain Charles Alan Hutt.
War Substantive Captain David Frew Wood.
Lieut. James Manson Knight.

DEATHS IN THE SERVICES

Lieut.-Colonel HENRY GEORGE LUTHER WORTABET, I.M.S. (retired at Bournemouth on September 19, aged 88. He was born in Syria on September 5, 1853, and was educated at the University of Edinburgh, where he graduated M.B., C.M. in 1871, proceeding M.D. in 1883. Entering the I.M.S. as surgeon in 1879; he became lieutenant-colonel after twenty years' service and retired in 1909. He served in Afghanistan in 1880, received the medal, and in the Burmese campaigns in 1886-8, taking part in the operations of the 4th and 6th Brigades, and gaining the Frontier medal with two clasps. He had been a member of the British Medical Association for fifty years.

Medical News

The activities of the Royal Medical Society of Edinburgh are proceeding as usual, though the war has necessitated the temporary abandonment of the annual dinner. The inaugural address for the forthcoming session will be delivered by Surgeon Rear-Admiral Sir W. I. de Courcy Wheeler on Friday, October 17, at 8 p.m. in the Hall of the Society. The title is to be "What Society has Gained by the Progress of Surgery." During the session addresses will be given by Colonel F. A. E. Croft, Prof. G. B. Fleming, Prof. A. T. Jurasz, Dr. J. Trueta, and Prof. Samson Wright.

The 1941 annual meeting of the National Society for the Prevention of Blindness (U.S.A.) will be held in New York City from December 4 to 6.

The Duchess of Portland has accepted the presidency of the London Ambulance Benevolent Fund. Founded less than three months ago, the Fund has already raised £2,500, and has been the means of help in over forty cases of distress among members of the regular and auxiliary Ambulance Service and their dependants.

Mr. Geoffrey Williams Carte, F.R.C.S., surgeon, London, has been commended for brave conduct in civil defence.

On September 11 the New Zealand House of Representatives passed the Crimes Amendment Act, substituting life imprisonment for the death penalty for murder and abolishing flogging.

Dr. H. D. Clementi-Smith has been elected a Warden of the Mercers' Company, the first, in order of civic precedence, of the twelve great Guilds of London.

The Department of Health of the City of New York is planning to establish an Institute of Scientific Research.

No 38

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 20.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1941					1940 (Corresponding Week)

* Includes paratyphoid A and B for Northern Ireland.

† Includes primary form in figures for England and Wales, London (administrative county), and Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, the birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales the recent decrease in the incidence of measles and whooping-cough and the increase in the incidence of scarlet fever and diphtheria were continued in the week under review. In Scotland scarlet fever was the only one of these diseases which showed an increase compared with the preceding week. A large relative decrease of 25% (196 cases) was recorded in the notifications of measles in England and Wales. This rapid rate of decline has been a feature of the trend of measles during the past sixteen weeks. The total cases of measles recorded in the last four-week periods were 40,656, 19,916, 8,743, and 3,478, showing rates of decline of 50, 56, and 60% on the preceding monthly totals. The number of cases of measles notified during the week reviewed was one-twelfth of that recorded in the corresponding week of last year.

The number of notifications of whooping-cough in England and Wales was 421 less than in the previous week. This was the third consecutive week that a decrease has been recorded, the rates of decline being 4.5, 10.5, and 15.5%. In Scotland a decrease of 47 in the number of cases of whooping-cough occurred. The experience of Glasgow (67 cases out of a total of 106) still dominates the returns for this country.

The rising trend of the notifications of diphtheria in England and Wales resulted in an increase of 40 on the total of the previous week. A decrease of 17 was recorded in Scotland, following four consecutive increases. A small increase (10 cases) was recorded in the notifications of scarlet fever in Scotland for the ninth consecutive week. In England and Wales an increase of 135 was notified. The incidence of paratyphoid and typhoid diminished, and the total cases were the smallest number recorded since the first week of July.

Cerebrospinal Fever

With the exception of an increase of 10 cases in Warwickshire and 5 cases in Middlesex, the notifications of cerebrospinal fever in England and Wales, which exceeded last week's total by 3, did not show any special difference from the previous week's distribution. In Scotland a relatively large increase, from 23 to 34 cases, occurred. The increase was due to outbreaks in the counties of Angus, Fife, and Midlothian. Slightly more than half the total was contributed by the cities of Glasgow 12, Edinburgh 4, and Dundee 2 cases.

Dysentery

The slight increase of 8 was recorded in the notifications of dysentery in England and Wales. Small local outbreaks occurred in Shropshire (Wem R.D. 12); Cornwall (Bodmin M.B. 8); Warwickshire (Rugby M.B. 8); Yorkshire, West Riding (Halifax M.B. 6 and Brighouse M.B. 6). In Scotland, where the notifications exceeded last week's total by 1, the chief outbreaks were those of Dundee 19, Glasgow 10, Lanark County 10, and Edinburgh 6.

Poliomyelitis

Twenty-eight cases of poliomyelitis were notified in England and Wales, a decrease of 25% on the total of the previous week. The chief centres of infection were Middlesex with 5 (Edmonton M.B. 2), and Oxfordshire with 4 cases, which were all notified in Oxford C.B. In Buckinghamshire, where the most serious of the recent local outbreaks occurred, 2 cases were reported after an interval of a week without one. Both these cases were notified in Slough M.B., and this area had 4 cases during the week ending August 23. Two cases each were notified in the counties of Cornwall, Devonshire, Hampshire, and Surrey. Eight cases, compared with 2 in the preceding week, were notified in Scotland. Glasgow, with 4, was the only area with multiple notifications.

Week ending September 27

Cases notified in England and Wales during the week were: scarlet fever 1,258, whooping-cough 2,247, diphtheria 1,066, measles 745, cerebrospinal fever 94, acute poliomyelitis 38, dysentery 89, paratyphoid 100, typhoid 32.

Universities and Colleges

UNIVERSITY OF SHEFFIELD

The following candidates have been approved at the examination indicated:

FINAL M.B., CH.B.—*Parts II and III*: H. Barrada, Pauline M. Hardcastle, L. Ishak, L. F. Q. MacLaine, Margaret E. Withers.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Arnott and Erasmus Wilson demonstrations and Museum lecture-demonstrations will be given at the College (Lincoln's Inn Fields, W.C.) as follows: October 13, Prof. A. J. E. Cave, the constitution of the skull; October 14, Mr. L. E. C. Norbury, benign neoplasms of the rectum; October 15, Prof. Cave, vascular arrangements of the head and neck; October 16, Mr. Norbury, malignant neoplasms of the rectum; October 17, Prof. Cave, lymphatics of the head and neck; October 20, Prof. Cave, surgical anatomy of the nasal fossa; October 21, Mr. R. Davies-Colley, diseases of the testicle; October 22, Prof. Cave, surgical anatomy of the mouth and jaws; Oct. 23, Mr. C. E. Shattock, tumours of the kidneys; October 24, Prof. Cave, surgical anatomy of the pharynx and larynx; October 27, Prof. Cave, surgical anatomy of the liver and bile ducts; October 28, Mr. Davies-Colley, tumours of the intestines; October 29, Prof. Cave, surgical anatomy of the kidney and ureter; October 30, Mr. Shattock, tumours of bone; October 31, Prof. Cave, surgical anatomy of certain nerves. All the demonstrations begin at 2.30 p.m., and are open to advanced students and medical practitioners.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES—EDITOR, *Ailology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Cancer in the Lower Animals

J. T. M. writes: I shall be glad if anyone can tell me what is the incidence of cancer among domesticated animals, particularly the cow, sheep, poultry; and fish. I have been told by an authority that cancer is rather common in poultry, affecting particularly their sexual organs.

Behaviour of Children and Adults under War Conditions

Miss EVELYN FOX, C.B.E., honorary secretary of the Mental Health Emergency Committee (24, Buckingham Palace Road, S.W.1), writes: This committee has been making an inquiry into the behaviour of children and adults under war conditions. Questionnaires have been sent out to child guidance clinics, mental treatment clinics, psychiatric wards of emergency hospitals, and to psychiatric social workers in the reception areas. This inquiry was intended to be only a preliminary survey, and before proceeding further the committee would be very interested to learn whether any similar investigations are being carried out, either by groups or by individuals, and if so would welcome opportunities of co-operation.

Income Tax

Expenditure on Books

"X. Y." refers to an answer in our issue of July 16, 1941, and asks for a note on the decision in *Simpson v. Tate*.

* The answer referred to was given on the understanding that the inquirer was in general practice and assessed under Schedule D; salaries, etc., are assessable under Schedule E, and the rule in that Schedule with regard to expenses is more stringent than the

corresponding Schedule D rule. Dr. Tate was a county M.O.H., and claimed to deduct subscriptions to certain professional societies. In his judgment Rowlatt J. said that "taking in professional literature and all that sort of expense which enables a man to keep himself fit for what he is doing are things which can none of them be allowed." This decision seems to cover the purchase of books if the income is assessable under Schedule E.

LETTERS, NOTES, ETC.

Irrigation in Treatment of Diverticulosis

Dr. BERNARD MYERS (London, W.1) writes: Diverticulosis is not an infrequent condition in older adults, not difficult to diagnose from the train of symptoms and confirmation by x rays. Not only constipation but the tendency to attacks of diverticulitis with the accompanying discomfort and pain is apt to cause depression, especially in the more severe cases. From my experience of these cases I suggest that the essentials of treatment are a non-irritating diet free from pips, skins of fruit, or other indigestible material, the daily taking of liquid paraffin in sufficient but not in excessive doses, and irrigation of the colon from time to time. Cases that receive this treatment have, I suggest, not at all a bad time, and can enjoy life reasonably and play games. With regard to liquid paraffin, I find cases differ to some extent, but, generally speaking, a tablespoonful thrice daily suits many sufferers; but to some this would be excessive, and less must be taken, as too much causes too frequent action of the bowels with much discomfort and accidents in clothes. Others need more, and I know of a well-marked case in a man over 60, who takes two tablespoonfuls every morning before breakfast and the same quantity before the evening meal, and keeps free now from attacks of diverticulitis provided his colon is irrigated at least every two months. Irrigation must be done only by real experts, as those not properly initiated into the method may cause great discomfort or even danger. I believe that many bad cases need irrigation once a month and possibly more often. When it is properly done the patient complains of no pain or discomfort, but, on the other hand, a feeling of great relief and well-being. It is surprising to see the material removed from a diverticulum after a careful irrigation. Sufferers from diverticulosis should not strain at stool; indeed, there should be no need if the dose of paraffin be well regulated.

The Blunt Needle

Mr. A. P. BERTWISTLE, F.R.C.S.Ed. (London) writes: A blunt needle is at once a source of annoyance and danger. The chief danger is that the needle may break in the tissues, requiring operative removal. A second danger is that it must pass through the tissues more like a saw than a knife. If the needle is obviously rusty micro-organisms may lodge in the crevices untouched by antiseptics, save those of low surface tension, though not by boiling, of course. Hypodermic needles are now made of stainless steel; they become blunt very often by the tip bending backwards, usually over the lumen, and also from excessive use. They can be sharpened with the aid of an oil-stone. Gone are the days when a matchbox was, surreptitiously, used for removing rust. With regard to suture needles, I have the authority of Messrs. Thackray for stating that stainless steel has so far proved unsatisfactory, since it will not harden or temper as well as carbon steel. (In the present emergency they have been asked not to draw on supplies available.) Prof. John Hilton in a broadcast said that safety-razor blades became blunt as the result of an invisible rust forming on the cutting edge, it being impossible to dry the edge perfectly with a towel. If, however, the blade is finally cleaned with a rag moistened with a thin cycle oil it will keep its edge twice as long. Applying this principle to suture needles, if the needle be drawn through a piece of chamois leather impregnated with thin oil several times after use it will be found that the needle keeps sharp much longer, a point of value in these hard times.

Disclaimer

Drs. J. ROBINSON and M. STOCK write from Manchester: Our attention has been called to a recent newspaper article concerning the treatment of influenza and colds in which our names appeared. We desire to state clearly that we have given no interview to the writer of the article or any other person, and that we had no knowledge of its proposed preparation or publication. We desire further to state that we take no responsibility for the nature or accuracy of the statements made or the facts alleged.

Corrigendum

In the report supplied to us of the meeting of the Association of Clinical Pathologists held at Cambridge on July 19 and published in the *Journal* of August 30 (p. 315) Dr. S. C. Dyke is recorded as having made observations on eosinophilia in glandular fever. Dr. Dyke was in fact discussing trichiniasis and not glandular fever, and he asks that this correction may be notified to our readers.

THE SCOPE OF OPERATION IN TREATMENT OF VARICOSE VEINS

BY

REGINALD T. PAYNE, MS., MD., F.R.C.S.

Surgical Assistant, British Postgraduate Medical School, Hammersmith; late Surgeon, Emergency Medical Service

The introduction of injection methods of treating varicose veins focused attention on an important and rather neglected disease which is responsible for much ill-health, disability, and inefficiency. During the past fifteen years or so not only has the stimulus of the newer methods shown the value of injection treatment but the experience gained has clearly indicated the place of operation in dealing with varicose veins. At the present time it is true to say that every case of primary uncomplicated varicosity, however severe, can be "cured." By "cure" is meant the obliteration of the entire varicose circulation either by injection or by operation, or by a combination of these two methods. Using the word "cure" in this restricted sense, then, there are few cases which cannot be "cured" relatively quickly and completely. This paper is based upon the personal experience gained in treating over 1,300 patients for varicose conditions of the lower limbs. An evaluation of the place of operation must not, however, be taken to imply any serious criticism of the efficiency of injection for the majority of cases. But time has shown that if *all* cases are to be treated efficiently, irrespective of the nature and extent of the disease, then operation must still have a place in the scheme of treatment.

Untreated varicosity is almost always a progressive condition. The speed of progress is determined by many factors: family history, build, age at onset, pregnancies, the nature of the veins themselves, the patient's occupation, etc. If the condition remains untreated, complications such as congestive phenomena, dermatitis, ulceration, bone involvement, the various types of phlebitis, and disabilities due to scarring, etc., may develop. With existing methods of treatment it should be possible to avoid all varicose complications. The cause of varicosity is still unknown, but the evidence suggests that hereditary and endocrine factors are probably the most important ones. The surgeon cannot cure or influence this innate tendency to varicosity, but by treatment he can bring about a cure of existing varicosities, and by obliterating the varicose circulation the progress of the disease can be slowed.

This paper is particularly concerned with the operative treatment of primary varicosity in the uncomplicated stage. Uncomplicated cases include all those up to the congestive stage but exclude those beyond this—namely, dermatitis, ulceration, phlebitis, etc. Surgical treatment may, of course, be required for some of these complicated cases, and although many of the principles which are described are also applicable, with modifications, to the advanced group of cases, the complicated ones are not considered here in detail. The term "primary varicosity" excludes all cases in which the varicosity develops secondarily to an obstruction of the deeper vessels—e.g., femoral thrombosis (Payne, 1938).

Varicose veins may be treated by injection in most cases, by operation alone in a few, and in some by operation and subsequent injection. The proportion of cases requiring either operation or operation and injection will, of course, be determined by the severity and nature of the condition.

Aim of Treatment

The anatomical aim of all forms of radical treatment, whether by injection or by operation, is to bring about obliteration of the varicose vessels either by thrombosis and organization or by actual removal. The physiological counterpart of this is the functional obliteration of the varicose circulation with its stagnation and congestive phenomena and the tendency to a to-and-fro movement of the blood. The clinical counterpart is the relief of symptoms, the removal of mechanical factors favouring the progress of the disease, and the elimination of the risks of possible complications. The anatomical, physiological, and clinical aims of treatment can be attained either by injection or by operation, or by a combination of operation and injection. No single method is suitable for all types of cases, but together they make it possible to treat every type of case that is met with clinically. Naturally the more severe or extensive cases are those which are likely to require operative treatment, but severity and extent are by no means the only criteria.

Indications for Operation

The indications for operative treatment may be absolute or they may be relative. Absolute indications are those conditions which offer no effective alternative to operation. Relative indications are those conditions in which operation may have advantages when compared with injection. In practice it will be found that cases fall into three groups from the point of view of treatment: first, those in which operation offers the only real prospect of cure; secondly, those in which operation offers better chances of more permanent cure; and, thirdly, those cases in which there are no indications for operation but which can be treated effectively by means of injections. The aim of operation is to obliterate all incompetent veins which are not likely to respond readily to subsequent injections. Throughout this paper the word "varicosity" is used to include all types of veins associated with valvular incompetence, irrespective of the presence or absence of tortuosity, gross dilatation, or thinning of the vein wall.

1. Absolute Indications

Anatomical Extent.—Involvement of the main internal saphenous vein above the level of the knee-joint is usually an indication for operative treatment, and the nearer the pathological change approaches the saphenous opening the stronger will be the indications for operation. This

assumes the presence of valvular incompetence in the affected vein, with reflux of blood on coughing, etc. Tortuosity and moderate size will in general be factors in favour of injection. Straight thick-walled veins (see Ectasia, below) or colossal tortuous veins will be factors in favour of operation.

Presence of Saphenous or Other Varices.—A large single varix or multiple varices do not give certain or permanent results with injection methods. All varices are commonest in the thigh, especially at the saphenous opening. A further point in favour of operation in these cases is that in many the dilatation is situated on veins which show mainly ectasia and are thick-walled, dilated, and straight, but incompetent.

Ectasia.—By ectasia is meant dilatation and increase in size of a vein associated with valvular incompetence, but the vein remains relatively straight and its walls are very thick. Ectasia thus differs from true varicosity, since in the latter the vein becomes tortuous and thin-walled; but valvular incompetence is just as pronounced in ectasia as in the case of tortuous veins, and the progress of the disease and the complications are common to both groups. Ectasia is especially likely to be found in young athletic males, but it is certainly not unknown in women. The condition may involve only the internal saphenous vein or it may involve all the superficial veins of the lower limbs. In practice ectasia is often found in the main saphenous vein in the thigh, while the calf veins show either a combination of ectasia and varicosity or pure varicosity. The presence of ectasia has important bearings upon the question of treatment. Veins which show ectasia do not respond at all well to injection methods; and I have had patients referred to me who have had twenty or more injections in such veins without producing any thrombotic response. Furthermore, if thrombosis does occur these ectatic veins are especially likely to recanalize during the course of a few months. And it is a fact of clinical observation that the more thin-walled and tortuous a vein the more certainly will it respond to injections and the more permanent will be the obliteration, whereas the thicker and straighter the vein the less likely is it to thrombose, and if thrombosis does occur it is much less likely to be as lasting as in the case of tortuous thin-walled vessels.

Size of Veins.—Huge masses of tortuous veins are often best treated by excision, especially when they are the size of the index finger or thumb. Thrombosis of such colossal veins occasionally produces considerable pain and discomfort, and the resolution of the huge thrombosed mass may take from four to six months to complete. Nevertheless, mere size is not necessarily a contraindication to injection treatment; but operative treatment has the advantages of being quicker and less painful and of giving a better cosmetic result.

Failure of Response to Injections.—From time to time cases are seen which have given no appreciable response to injection treatment. It is usually found that cases that have not responded to adequate amounts of injection fluids are examples of ectasia rather than of true varicosity. In a few cases colossal varicosities do not thrombose owing to the diluting effects on the injection solutions.

Recanalization after Injections.—There is no doubt that it is possible for recanalization of an injected and thrombosed vein to occur. Recanalization is particularly likely to develop when injection treatment has been carried out and patent proximal but incompetent veins are left untreated between the site of injection and the saphenous opening. It is also likely to develop in ectatic veins in which the thrombosis has been incomplete or transient, and it may occur when incomplete treatment has been given to a huge sponge-work of veins with large numbers of

collateral channels. In all cases this recanalization is due to the reflux of blood from above and to the opening up of the thrombosed or partially thrombosed veins. Thus recanalization means either that unsuitable veins have been injected or that injection treatment has been inadequate, and it is invariably associated with patent proximal and incompetent veins. An incompetent internal saphenous vein in the thigh, whether associated with ectasia or varicosity, is often overlooked by the patient and by his doctor, especially when much subcutaneous fat is present. The patient complains of the obvious varicosity in the calf, but the incompetent thigh veins may not have been noticed. Injections to the calf veins in such a case may be followed by recanalization.

2. Relative Indications

The presence of certain conditions or factors may be relative indications in favour of operation as opposed to injection.

Rapidity of Development.—In certain cases the varicose condition develops very rapidly and almost as an acute process. This may happen at any age, but some of the most rapid cases I have seen occurred in women at the time of the menopause. Injection treatment in such cases is little more than symptomatic, and there is really a contest between the therapeutic thrombosis and the development of fresh varicosities. Operation in such cases may be the only practicable solution.

Family History.—The family history of varicosity and its complications must be taken into consideration when weighing the advantages of injection and operation. A bad family history obviously favours the more radical method.

Age.—The age of the patient must of course be considered. Relatively rapid development at an early age will favour operative treatment.

Occupation.—Employment which involves a good deal of standing rather than rhythmical walking may have to be taken into account as a factor favouring operative treatment. But the question of employment will rarely be the only indication for operation.

Geographical Considerations.—If a patient is going to a part of the world where he cannot get skilled attention, operative treatment may give better prospects of prolonged and permanent freedom from recurrences and complications.

Congestive Phenomena.—The presence of purplish discoloration and distended varicules on the feet and over the internal malleolus or inner and lower part of the shin indicates a serious degree of reflux in the saphenous system. These congestive phenomena must be taken as warnings that the saphenous circulation is inefficient and that the next stage will be dermatitis or ulceration. Incompetence of the main saphenous vein in the thigh is present in many of these cases. On these grounds there are often strong indications for operative treatment.

Other Complications of Valvular Incompetence.—The other complications of valvular incompetence—dermatitis, ulceration, and phlebitis, etc.—are not considered in detail, but it is obvious that when dermatitis and ulceration occur the indications for operative treatment already given may apply with added force.

Future Pregnancies.—Patients sometimes come under observation who have had trouble with veins or with phlebitis in a previous pregnancy and are contemplating another. Others who are contemplating a first pregnancy have had similar trouble. In some cases operative treatment may offer the greatest freedom from varicose trouble during pregnancy and the puerperium and in the future.

The Aim of Surgery

Whatever method of treatment is employed its object is always the same—namely, to obliterate the whole varicose circulation. This object may be attained partly by ligation and section of veins, partly by excision, partly by thrombosis between ligatures or excisions, partly by subsequent injections, or by injections alone. The treatment of each patient must be assessed in the light of the clinical history and of clinical examination. If there are indications in favour of operative treatment an attempt must be made to determine both its scope and the part to be played by subsequent injections. At the close of any operation the surgeon should be satisfied that any remaining veins can be treated readily and effectively by means of injections. No case is too severe for a combined attack by operation and injection, and at the completion of treatment it should be possible to say that 100% or nearly 100% of the varicose circulation has been put out of action in one way or another.

Pre-operative Treatment

The patient is admitted to hospital the night before operation. In an extensive and bilateral case both lower limbs are shaved, as well as the abdomen below the level of the umbilicus. The patient then stands in a good light and the veins are marked in with skin ink, the composition of which is as follows:

R	Ac. pyrogall.	1 gr.
	Sp. vin. meth.	20 c.cm.
	Liq. ferri perchlor.	2 c.cm.
	Acetone	10 c.cm.
	Ac. hydrochlor.	1 drop
	Ft. sol.					

The main veins are inked in throughout their entire course, and all large varices and collaterals are indicated, as well as any other veins upon which it is decided to operate. The marking-in must include veins on both the front and the back of the lower limbs.

The whole region is prepared with spirit and iodine and wrapped in sterile towels. The skin preparation is repeated the following morning. The importance of careful preparation and asepsis in all operations on the subcutaneous veins cannot be too strongly stressed. Special attention must be directed to areas of skin showing atrophic change over underlying attached veins and to areas showing congestive phenomena. Areas of definite dermatitis or ulceration should be covered completely by sterile gauze rolls.

Anaesthesia

General anaesthesia is the method of choice, and gas-oxygen and ether are usually adequate. There are two objections to the use of local anaesthesia for multiple ligation or excision operations: first, in a bilateral case of average severity, in which operation has to be carried out at five or six sites in each limb, local anaesthesia takes considerably more time; secondly, although ligation can readily be performed under local anaesthesia, it is more difficult to use this method for the excision of an irregular mass of large tortuous veins in the thigh or calf.

Operative Technique

The nature of the operative procedures to be carried out will have been decided on at the time of examination and reviewed when marking in the veins. Whenever operative treatment is indicated I believe that minimal operations should be avoided. By "minimal" is meant a ligation at the saphenous opening and possibly at one other site. Operations of this type, even when combined with subsequent injections, rarely lead to complete obliteration of the varicose circulation. On the other hand, there is nothing

to suggest that surgery should be maximal. What should be aimed at in the individual case is a series of operations which will lead with subsequent injections to thrombosis and obliteration of the whole varicose circulation.

Position.—The patient is placed on the operating table in the dorsal position and the whole region below the umbilicus is again cleaned, and the feet or any other parts where operation is not required are covered with sterile towels. All anterior sites must be dealt with first, and if posterior veins are present the patient must be turned over on to his face.

Incisions.—It is preferable to start proximally and to work distally. The first ligation will be at the saphenous opening and the last in the lower third of the saphenous vein in the calf. Incisions must be planned in relation to the natural folds or creases, the nature of the local operation to be carried out, and the condition of the skin and subcutaneous tissues. Incisions in the line of the limb or in the line of the veins should be avoided.

The Affected Vein in Relation to Operation.—What is to be done at any particular site? This must be determined by the nature of the vein at that site. Ligation and division is indicated in the case of a straight or relatively straight vein, particularly if this is thick-walled, and in the case of a single large tortuous vessel. A single varix should be excised, the main vein ligatured above and below, and any collaterals also ligatured. A mass of tortuous veins with many anastomosing channels calls for a free excision. In many cases it will be found that ligation is required at the saphenous opening, in the mid-thigh, just above the level of the knee-joint, and in the lower third of the leg. In the upper third of the calf a more extensive excision is often required on account of anastomosing channels or multiple ectatic veins.

(a) **Ligation.**—The vein is exposed by an incision placed obliquely across its direction, the margins of the wound retracted, and the vein ligatured with No. 1 catgut at the upper and lower limits of its exposure. The intervening one to two inches of the vein is excised, and the amount of this depends upon the exposure. The operation is thus not merely a ligation, but is a ligation together with the removal of the exposed segment of vein. In the case of very thick and relatively straight incompetent veins, more rather than less should be excised. If a localized varix is present in association with a straight vein, this is an indication for local ligation above and below together with excision of the varix. At the same time any entering collateral vessels, often deep veins, must also be ligatured. The number of ligations must be determined by the nature of the veins, their extent, and the probability of response to injections of the remainder. Care is needed in planning incisions. An exposure which enables the main vein and two or three large collaterals to be ligatured at the same time is preferable to one which only allows ligation of the main trunk.

(b) **Excision.**—A more extensive excision will be required under the following conditions: (1) colossal and usually tortuous veins, especially if adherent to overlying atrophic skin; (2) a mesh-work or sponge-work of big tortuous veins with large numbers of collateral and anastomosing channels; (3) the presence of several parallel or anastomosing ectatic veins.

In planning each operation regard must be paid to the nature and extent of the veins, the condition of the skin, and the position of the resulting scar. The local exposure should be adequate, and any adherent skin should be included in an ellipse. All veins are ligatured at the upper and lower limits of the wound, and the intervening tissue, together with the skin and subcutaneous tissue, is excised.

Closure of Wounds.—Haemostasis must be perfect. Subcutaneous fat must be closed with interrupted catgut sutures and all dead space obliterated. The skin is closed with interrupted sutures of fine silk-worm-gut. In all cases care

must be taken to avoid having a ligatured vein stump immediately adjacent to the skin incision. This can always be secured by careful planning of the skin incisions.

Dressings.—The various wound sites are covered with gauze or towels at the close of each local operation. At the completion of the whole operation each wound site is painted with iodine. Gauze pads are placed over the inguinal wounds and the limbs firmly bandaged with roller gauze from the ankles to the groins. A thick layer of wool is applied and the limbs are bandaged upwards, ending in a spica at the groins.

Post-operative Care

Position.—As soon as the patient is returned to bed the limbs are placed on pillows and between towelled sandbags, and covered with a cradle. The dorsal position and the limited movement possible until the stitches are removed are usually the patient's most serious complaints during the post-operative period.

Pain.—The operation causes very little pain. Morphine is required on the first night but rarely afterwards, and after the second day the patient is usually very comfortable. Those with very large veins may get more discomfort from sites of intervening thrombosis than from the actual wounds themselves.

Dressings.—After all extensive operations dressings should be carried out on the third day. This is especially necessary where large excisions have been performed, and early dressings may avoid the risk of a collection of serum. The renewal of dressings and the reduction in bulk also add to the patient's comfort. Usually only one dressing is required before the removal of the stitches, but occasionally a second is necessary on the fifth or sixth day.

Stitches.—These are removed on the seventh or eighth day, depending on the number and size of the incisions. If a second dressing is carried out about the fifth or sixth day it is often possible to remove alternate stitches at this stage.

Subsequent Nursing.—Sandbags are not required after the removal of the stitches, and the patient is allowed to have the limbs off the pillows one to two hours daily, and this time is gradually increased. He is allowed up for half an hour on the ninth or tenth day, and by the twelfth to the fourteenth day he should be able to walk short distances and be ready to leave hospital. At this stage the various wound sites are dressed with gauze and covered with elastoplast, which encircles the limbs except in the region of the groins. These dressings are left on about a week, by which time all wounds are firmly healed. In order to get rid of the remains of skin paint, iodine, and desquamating epithelium the patient should have a warm soapy bath on two or three successive evenings. At the end of a month from the time of operation recovery from its effects is complete.

Post-operative Injections

Patients are seen three to four weeks after operation. By this time it is possible to tell which veins are thrombosed and which are still patent. It is probable also that only small tortuous veins will have been left for injection after a well-planned operation. Personally I prefer to use quinine urethane for this on account of the greater certainty of its thrombosing action. At this stage injections may be carried out daily, alternating the limbs, but longer intervals will be required when larger veins have to be treated. The details of injection treatment using quinine urethane solution have previously been described (Payne, 1936). Treatment on these lines can usually be completed in from two to four weeks.

In the few cases in which no injections are required the patient may return to work three to four weeks after opera-

tion. If injections have to be carried out subsequent to operation the question of resumption of work must be decided by the probable length of the treatment and the nature of the patient's work. It is usually possible for patients to carry on with other than very heavy work throughout the period of injections.

Subsequent Review of Patients

It is advisable, whenever possible, to see patients at intervals of three, six, and twelve months after completion of treatment. Even the most severe case of varicose veins can be treated by operation and injection and the whole varicose circulation obliterated in from six to eight weeks, with the certainty of at least many years' freedom from any important recurrence. But the *tendency* to varicosity is inherent and persisting, and the more severe the initial condition, and the younger the patient's age at onset, the greater will be the need for periodic review at intervals of a year or so. Once varicosity is established, mechanical factors also come into play and tend to involve adjacent veins. The obliteration of the varicose circulation not only gets rid of the affected veins but also slows or retards the progress of the condition by eliminating aggravating mechanical factors.

Prognosis

The cases which have been discussed in this paper are chiefly those in which a complete obliteration of the varicose circulation would have been impossible without operation, and they therefore represent the more severe types. The *tendency* to varicosity is inherent and persisting, and the most important factors attending the prognosis in the individual case are as follows:

1. A bad family history of varicosity and its complications.
2. The rapidity of development of the condition.
3. The age of onset. Rapid development during adolescence is usually a bad prognostic sign.
4. The actual age of the patient. In general the older the patient the slower the progress of the disease.
5. The nature of the veins. The sponge-like type of diffuse veins with little anatomical arrangement is one of the worst possible forms. Another bad type is extensive ectasia involving all the superficial veins. In these types extensive operative treatment is alone likely to cure the condition.
6. The period of onset in women, whether during adolescence, pregnancy, or the menopause.
7. The possibility of further pregnancies in women.
8. The nature of the subcutaneous tissues. A large amount of flabby lax subcutaneous fat is a bad prognostic sign when compared with a small amount of firm subcutaneous tissue.
9. Occupation. Employment involving a great deal of standing or irregular walking is much more harmful than that which involves regular rhythmical exercise.
10. Treatment. Obviously one of the most important factors governing the prognosis is the completeness of treatment. The tendency to varicosity cannot be eliminated; but by securing complete obliteration of the varicose circulation the progress of the disease is slowed and retarded by the elimination of aggravating mechanical factors.

Summary and Conclusions

The adequate treatment of primary uncomplicated varicose veins involves the complete obliteration of the varicose circulation.

Injection treatment will secure this in most cases; but operation, or more often a combination of operation and subsequent injections, is necessary for some cases, particularly the more advanced ones.

No case is too severe for the combined treatment.

The absolute and relative indications for operative treatment are given.

The details of pre-operative treatment, operation, and post-operative care are described, and subsequent injection treatment is outlined.

The whole varicose circulation can be completely obliterated in from six to eight weeks from the time of operation, and the patient rendered fit even for heavy work.

Patients with the severe type of varicosity should be reviewed at intervals of a year or so whenever possible.

The factors governing prognosis are outlined. Of the controllable factors the most important is the completeness of the obliteration of the varicose circulation.

THROMBOSIS IN THE SUPERIOR LONGITUDINAL SINUS FOLLOWING CHILDBIRTH

BY

J. PURDON MARTIN, M.A., M.D., F.R.C.P.

Physician to Out-patients at the National Hospital for Nervous Diseases, Queen Square; Neurologist, British Postgraduate Medical School

Thrombosis in the superior longitudinal (sagittal) sinus has long been known to pathologists as one of the conditions that may give rise to fatal cerebral symptoms in the puerperium or after abortion. With the exception of a case reported by Symonds in 1937 little has been written in English on the subject for a good many years past, but five cases were published in the *Zeitschrift für Gynäkologie* between 1925 and 1928, and these and seven others were collected by Mondré (1928). Other verified instances are to be found among the numerous cases of paralysis associated with pregnancy collected by von Hösslin (1904, 1905). In none of these instances was the diagnosis made during life. Headache and gradually increasing coma were the outstanding symptoms; paralysis was not always observed; convulsions occurred in some cases; and amaurosis is mentioned by Zangemeister (1925) in his description.

Within the last few years cases in which the superior longitudinal sinus is obstructed have become subject to clinical diagnosis. This has resulted partly from observation of these puerperal cases, but chiefly it has been a consequence of Symonds's studies of "otitic hydrocephalus"—another condition in which this sinus is thrombosed. Now that they can be recognized clinically it appears that puerperal cases of sagittal sinus thrombosis end more often in recovery than in death, but so far only one non-fatal case has been published (Symonds, 1940; Martin and Sheehan, 1941). Clinical accounts are given here of three cases which are believed to be of this nature: death ensued in one of them, but it was not due to the thrombosis in the sagittal sinus. In addition to these three I have seen during the last five years two cases in which similar symptoms were associated with stillbirth, a case following abortion in which the right cavernous sinus was evidently thrombosed, and a case of long-standing residual disabilities from a puerperal illness which must have involved very extensive thrombosis in the superior longitudinal sinus.

The moment is appropriate for consideration of these cases because Batson's work, recently published, has provided the probable explanation of the means by which thrombosis following childbirth or abortion is determined to this seemingly extraordinary site.

Applied Anatomy

The diagnosis of thrombosis in the superior longitudinal sinus depends on the signs of raised intracranial pressure and the signs of obstruction of superior cerebral veins.

Signs of Raised Intracranial Pressure.—It will be recalled that the sinus is triangular in cross-section (see diagram)

Diagram showing the superior longitudinal sinus in cross-section.

In many subjects numerous trabeculae cross it, and in some instances a continuous membrane divides it horizontally for a portion of its length (O'Connell, 1934). At its upper angles irregular lateral diverticulae—the lacunae laterales—contain within their walls numerous Pacchionian bodies through which the cerebrospinal fluid is absorbed into the blood stream. If the circulation in the sinus is obstructed, or if the upper story of the sinus becomes filled with clot, absorption of the cerebrospinal fluid is prevented and the intracranial pressure consequently rises, with the production of headaches, papilloedema, and perhaps vomiting. The significance of this hydrocephalus as an indication of sinus thrombosis was recognized by Symonds (1937).

Signs of Obstruction of Superior Cerebral Veins.—The sinus receives the superior cerebral veins, and these enter its walls near the inferior angle. If a thrombus occludes the whole cross-section of the sinus opposite the entrance of a vein, or if it is situated in the trough of the sinus or extends down into the trough, it may obstruct one (or more) of these veins. Thrombosis of the affected vein is then likely to occur. Many thrombi, however, are not so situated as to obstruct veins. Moreover, it seems that an obstructed vein does not invariably become thrombosed, and this is doubtless because of the easy collateral circulation. When thrombosis of an obstructed vein occurs it gives rise to paralysis corresponding to the area of cerebral cortex which the vein drains, and this paralysis may or may not be ushered in by a series of convulsions. Convulsions seem to be less usual when venous thrombosis is secondary to obstruction in the sinus than they are when a vein is thrombosed primarily. By no means all cases of thrombosis of the superior longitudinal sinus are recognizable in the present state of our knowledge, and it is certain that a large thrombus may exist in the sinus without giving rise to any clinical signs.

Case I

This is an instance of the most straightforward type of case.

Fits seventeen days after delivery; right hemiparesis; papilloedema; complete recovery.

An 8-para aged 40 was confined on June 25, 1936, labour being normal and the puerperium uneventful. During the night of July 12-13 she had four fits, and next day was admitted to hospital. She was then conscious, but in a stuporous state, was very drowsy, and barely understood what was said to her. She had paresis of the right arm and slight drooping of the right side of the face; there was also slight weakness of the right leg, and the right plantar reflex was extensor. The temperature on admission was 100° F. and the pulse rate 110. There was no neck rigidity. Examination of the heart disclosed nothing abnormal. The blood pressure and urine were normal, as were

the lungs and abdomen. Lochia had ceased. The C.S.F. was normal except that it contained a considerable number of red blood cells; but it was thought to be under increased pressure, and examination of the ocular fundi a few days later showed slight swelling (1 D) of both optic disks and a few small haemorrhages over the left one.

On the second morning after admission the patient had several more fits, with twitching beginning in and being chiefly confined to the right arm. The next day she was conscious enough to obey simple commands; her right arm was then found to be almost completely paralysed and the weakness of her face and leg had increased. Her pupils were unequal, the right being the greater. Her temperature was normal. A week later she was very much better. She was quite alert and clear mentally, her right arm had regained a great deal of its power, and her right leg was normal. Her papilloedema, however, remained, and fresh haemorrhages occurred, this time at the side of the right disk. A fortnight after the onset her right arm could be considered normal. As soon as she was well enough she complained of pain in the right leg, but nothing abnormal was seen on examination of it. Later, when after nearly eight weeks she began to get up, this leg swelled, and it is possible that there had been some thrombosis in the deep veins.

She was discharged from hospital, feeling well, after three months, but it was another six weeks before her ocular fundi were passed by the ophthalmologist as clear.

Comment.—This case showed symptoms of the two groups mentioned. The sudden onset of convulsions in the right side, followed by right hemiplegia and accompanied by the presence of a small quantity of blood in the C.S.F., can be attributed to thrombosis of a vein on the surface of the left cerebral hemisphere. The symptoms and circumstances are identical with those in certain puerperal cases described by Martin and Sheehan (1941), in which such thrombosis of veins was verified post mortem. The co-existing papilloedema showed that the intracranial pressure was considerably raised, and this would not be caused by thrombosis of veins alone. It is, however, accounted for by prevention of the absorption of cerebrospinal fluid by clot in the superior longitudinal sinus. The differentiation from cerebral tumour could not be made with certainty in the early stage, but the blood cells in the C.S.F. and the association with childbirth were points greatly in favour of thrombosis, while the normal protein content of the C.S.F. was a point against tumour. With cerebral arterial embolism, thrombosis, or haemorrhage there would have been no papilloedema.

Case II

Femoral thrombosis seven days after delivery. Two weeks later, abrupt onset of visual disturbance and headache, followed by left hemiplegia; papilloedema; considerable recovery, but death in consequence of a spinal lesion.

The patient, aged 43, was delivered of her seventh child on June 12, 1938. On June 19 she had thrombosis in her left thigh; this was treated with hot fomentations, and she got up on June 25. On July 3 she went to church, and on returning home "felt a blackness behind the eyes" and had a headache. She went to bed and slept. The next morning on waking she could not see, and could not move her left arm and leg satisfactorily.

The patient was admitted to hospital the same day. She was then unable to see light and her pupils were dilated and did not react to light. She had weakness of the left arm and slight weakness of the left side of the face. The tendon reflexes were exaggerated on the left side; the left plantar reflex was extensor and the right one was weakly extensor also. Nothing abnormal was found in the heart, lungs, abdomen, or urine. The lochia had ceased. On July 8 she developed signs of a spinal lesion at the sixth dorsal segment, with complete paralysis of both legs, loss of sensation up to the lower ribs, and incontinence of urine and faeces. Meanwhile some vision had returned, but her optic disks were swollen and there were haemorrhages on the right

one. Paralysis of the left arm had become almost complete. Mentally she was rational and fairly alert. A week later her sight was much better and the visual fields seemed full, but the papilloedema remained. During the next few weeks the condition of the patient's left arm improved greatly, but as a result of the spinal paralysis her general condition gradually deteriorated, and she died on September 28, 1940. No post-mortem examination was made.

Comment.—Signs of intracranial pressure (papilloedema and headache) and hemiplegia indicated thrombosis of the superior longitudinal sinus. The sequence of events suggests that a clot present in the sinus had suddenly occluded it and that extension of the clot had afterwards gradually obstructed the mouth of a vein which drained the motor area of the right cerebral hemisphere.

The severe disturbance of vision at the onset of the illness calls for some comment. A somewhat similar disturbance will be described in the next case also, and, as has already been mentioned, amaurosis occurred in at least one of the German cases in which massive thrombosis of the superior longitudinal sinus was found post mortem. It seems most likely that this amaurosis is due to acute venous congestion of the optic disks consequent upon the abrupt rise of intracranial pressure which results from occlusion of the longitudinal sinus. There is no reason to suppose that the ophthalmic veins are affected more directly by thrombosis in this sinus: the disturbance cannot be satisfactorily explained by postulating venous lesions or congestion in the occipital lobes, nor would such a supposition account for the loss of the pupillary reaction to light which was observed in this case. Here and in Case III the sight was largely restored within a week or two while papilloedema was still present. I have encountered similar, though less severe, amaurosis in another case of sinus thrombosis in which the intracranial pressure was 200 mm., and in that instance also the vision quickly improved, although the intracranial pressure remained high and papilloedema persisted. We must suppose that after the sudden onset circulatory conditions within the nerve head adapt themselves in spite of the continuance of a high intracranial pressure.

In nearly all the cases of primary venous thrombosis described by Martin and Sheehan convulsions marked the onset of the illness and ushered in the paralysis, but in this case the hemiplegia developed without convulsions. There is some reason to believe that convulsions are less common if the sinus is occluded before the vein. An explanation of this may possibly be found in the fact that obstruction in the sinus leads to "opening up of the collateral venous circulation, so that when the mouth of a vein becomes blocked at the sinus the vein itself may not become thrombosed and venous congestion in its drainage area may be much less intense. The absence of convulsions may, however, simply be due to the gradualness of the onset of the paralysis and of the obstruction causing it.

The diagnosis in Case II admits few alternative suggestions. The suddenness of the onset strongly indicates a vascular lesion, and there are not many that would cause papilloedema. In particular, arterial embolism would not account for it.

The spinal lesion is an unusual complication on which I do not wish to comment here, beyond stating that it, too, was probably due to venous thrombosis, and its occurrence does not modify the diagnosis of the cerebral condition.

Case III

In this case the signs of cerebral venous thrombosis were not at first evident. Some clinically similar cases that were fatal are recorded in the literature.

Sudden onset of stupor. Amaurosis, headache, vomiting, papilloedema. Word-blindness. Recovery with residual symptoms.

This patient was confined on August 28, 1938, and ten days later one leg (? which) became painful and remained so until her admission to hospital on January 1, 1939. Both legs were then greatly swollen, and there were tender veins in the right thigh and in the left calf.

On January 12 she was found in a stuporous condition. When roused she carried out simple commands but "rambled." No paresis of her limbs was found. The next day she was still more drowsy and could not be made to understand what was said to her. She had no paralysis. The drowsy and stuporous state lasted for more than a week. Occasionally she mumbled incoherently. Eight days after the onset she was more sensible and said she had a headache. She complained that her sight was "faint" and that she could not recognize the ward sister. She vomited twice on that day (? before), and the margins of her optic disks were blurred. The drowsiness gradually passed off in the course of another week; but headache continued, and she still complained that her sight was misty, though it had improved. Her general condition and her sight gradually became better, and by the end of another month she seemed very well, but was unable to read; she could write, but could not read what she had written (word-blindness). Her acuity of vision was about normal and she could recognize small objects at a distance; her visual fields were full. When she left hospital after a stay of twelve weeks her papilloedema had entirely subsided.

Eighteen months later she was readmitted, having had two fits and become weak in her legs. Her word-blindness was still present. Her legs were slightly weak and spastic, with typical reflex signs, and her abdominal reflexes were absent. She was discharged much improved after a fortnight.

Comment.—In this case the connexion with childbirth is less immediate, but the series of events is continuous. During the first admission her superior longitudinal sinus was probably obstructed by clot, and hydrocephalus was thus caused; to this obstruction her prolonged drowsiness or stupor must be attributed. Her earliest visual disturbance was probably due, as has been said, to venous congestion of the optic nerve heads. It would seem that about the same time at least one superior cerebral vein was blocked, thereby giving rise to her word-blindness. In this case also the absence of convulsions is to be noted. Eighteen months later further thrombosis evidently occurred, causing some venous obstruction more anteriorly, with consequent temporary weakness of the legs. Two features of interest are the presence of a permanent residual disability and the occurrence, after a prolonged interval, of signs suggestive of further thrombosis. I have seen two other probable cases with severe residual disabilities, and in both of them the history indicated that there had been more than one acute attack.

Pathology

The form of the clot in the longitudinal sinus which may give rise to such symptoms is subject to great variation. In a number of the fatal cases a massive clot has been found filling the whole sagittal sinus and even the lateral sinuses as well (Mondré, 1928), but we can exclude such conditions in considering these less severe cases. There may, however, be a massive clot filling a portion of the sinus. Alternatively there may be multiple mural thrombi, some becoming large enough to obliterate the lumen, as in Symonds's (1937) case and in several of the older instances (Collier, 1891). Martin and Sheehan described a long "rat-tail" thrombus swimming free in the blood stream, except for an attachment to the wall of the sinus at one point, and such a clot might enlarge until it occluded the sinus. Other conditions which may occur have been described in non-puerperal cases—e.g., a continuous clot along the roof of the sinus, leaving the trough unobstructed (Bailey and Hass, 1937), and a layer of

clot on the walls, with a channel for blood persisting in the centre (Gowers, 1892-3).

The primary thrombus is usually in the longitudinal sinus, but it may be in one of the lateral sinuses, or clot may extend into the longitudinal sinus from a vein (Virchow).

Diagnosis and Clinical Variations

The principles for the diagnosis of clot on the superior longitudinal sinus have already been given, and if signs of raised intracranial pressure and signs of cerebral venous thrombosis coexist its presence may be assumed. Granted that there is no severe heart disease to provide a source of emboli and that the blood pressure is within normal limits, venous thrombosis is the most probable cause of hemiplegia occurring during the puerperium (von Hösslin). If this be remembered, and if papilloedema be looked for, the diagnosis will seldom be missed. Cerebral tumour is the most likely condition to cause confusion, and it may not always be possible to exclude it from the diagnosis at the beginning. A little blood in the cerebrospinal fluid on microscopical examination is strongly in favour of thrombosis, while with tumour an increase of the protein content is usual. Meningitis may have to be considered, and this can be excluded by examination of the cerebrospinal fluid.

It is not necessary for the diagnosis that both the principal groups of signs should be present. As with otitic hydrocephalus, there must be cases in which no thrombosis of veins occurs. The sudden onset in the puerperium of signs and symptoms of increased intracranial pressure should therefore arouse a strong suspicion of thrombosis in the longitudinal sinus, especially if they are accompanied by a drowsy or stuporous state. In a severe case of this kind the symptoms would be the same as in Case III without the residual word-blindness—namely, drowsiness or stupor, headache, amaurosis, and papilloedema. On the other hand, there are cases in which the intracranial pressure is not raised and the symptoms are exclusively those of venous thrombosis. If the symptoms merely indicate thrombosis of a single vein it is impossible to carry the diagnosis further, although clot may be present in the sinus; but if there is evidence of two or more superior cerebral veins becoming thrombosed, and especially if they are on opposite sides of the brain, there is a strong presumption that the veins are being obstructed by clot in the sinus. The validity of this deduction is illustrated by the fatal case described by Symonds (1937), in which there was paralysis first of the left arm, then of the right side of the face, and later complete left hemiplegia; there was no papilloedema; the cerebrospinal fluid was slightly bloodstained but its pressure was normal; post mortem there were mural thrombi of different ages in the longitudinal and lateral sinuses.

In cases with less extensive clot there may be neither any severe rise of intracranial pressure nor venous obstruction, and in the present state of our knowledge such cases are not recognizable. Some impairment of C.S.F. absorption may cause headache and nothing else, but there must be a number of cases in which relatively small clots on the walls or roof of the sinus give rise to no symptoms at all.

Treatment

When symptoms have appeared the treatment that is indicated is (1) to allay convulsions if they are present, (2) to reduce intracranial pressure, and (3) to prevent further thrombosis.

To allay convulsions a dose of three grains of luminal should be given, by mouth or by injection according to whether the patient is conscious or not. It may be repeated

as required at intervals of six hours. For the reduction of intracranial pressure the same palliative measures may be used as in cases of cerebral tumour—namely, the intravenous injection of glucose solution (50 to 100 c.cm. 50%) or an enema of concentrated magnesium sulphate solution (3ij-3iv). Symonds (1937) used frequent lumbar punctures in cases of sagittal sinus thrombosis resulting from ear disease; and in the first few days, especially if amaurosis is present, this is perhaps the most advisable procedure, because the pressure of the cerebrospinal fluid can be measured at the time of the puncture and can definitely be reduced temporarily to a normal level; it should be brought down to 100 mm. To prevent the thrombosis spreading the only means at our disposal is the administration of heparin, and of this I have no personal experience. In recent articles Dockeray and Kawerau (1940) and others have described the giving of this drug by the method of continuous intravenous drip, but if this method is not available repeated injections may be used.

Aetiology

In the active period of life cases such as these are extremely rare apart from child-bearing, and the association with child-bearing is so constant that it cannot be mere coincidence. Difficult labour, manual removal of the placenta, post-partum haemorrhage, uterine sepsis, and other complications of delivery can be exonerated as causes except in so far as they may give rise to pelvic or femoral thrombosis. In nearly all the obstetrical cases of longitudinal sinus thrombosis that I have seen there has been evidence of venous thrombosis elsewhere in the body, and the same has applied in many, if not all, of the fatal cases that have been described. Can it be that the clot in the longitudinal sinus is in some way "metastatic"—that some fragment transmitted from elsewhere forms the nucleus of a new clot? The superior longitudinal sinus would be a likely place for any element carried in the blood stream to settle, because the flow of the blood there is so slow that it would probably be deposited, and because the walls of the sinus are rough and irregular, with many small depressions in which it might lodge.

I had written this paper and stopped baffled at this question when I became acquainted through an annotation in the *British Medical Journal* with certain findings of Batson (1940). This worker, interested in the distribution of metastases from prostatic carcinoma, investigated the connexions of the pelvic veins by injecting radio-opaque material into them. He found that in addition to their known connexions with the caval system, these veins had free anastomosis with the veins in the vertebral canal and around the vertebral column, and that when material was injected into the veins in the pelvis of the cadaver this vertebral plexus of veins provided a free pathway for it right up to the dural sinuses. "We . . . expect to find fairly well filled such veins and sinuses of the cranial cavity as the superior longitudinal sinus, the cavernous sinus, Trolard's anastomotic vein, and others." Carrying this investigation further, Batson injected radio-opaque material into the dorsal veins of the penis of a monkey and showed that it followed the same paths as in the cadaver. If the flow to and in the inferior vena cava was obstructed by compression of the abdomen by means of a towel tied round the animal, some of the thorium medium passed into the vertebral system of veins, and could be followed in the x-ray films upwards past the zone of compression. Batson deduced from his experiments that during coughing and straining blood was actually squeezed out of the abdominal (and pelvic—J. P. M.) veins into the vertebral vein system. In the parturient woman the conditions for the upward passage of any blood-borne fragment are still more favourable than in Batson's monkeys. In

fact, when she strains on the bed-pan they seem to be simply ideal. Because of the movements of the bowel and bladder and her active straining, that is the time when a fragment of clot is most likely to be dislodged; because of her straining, to which is added compression of her abdomen by a firm binder, such a fragment would be directed into the vertebral vein system and propelled upward by the movements of blood induced by her repeated straining. As if those factors were not enough, her posture on the bed-pan calls in gravity to aid the process. It is well known that fragments of clot are liberated from thrombosed pelvic or femoral veins and give rise to pulmonary embolism, and it would be remarkable, under the conditions prevailing, if they did not sometimes pass into the vertebral venous system, and occasionally reach the cranial cavity.

In a cerebral vein a fragment of clot might cause actual embolism (plugging), but in the longitudinal sinus it obviously cannot do so, since all the means of entrance into the sinus are narrower than the channel itself. It is therefore necessary to suppose that a deposited fragment would serve as the nucleus of a new clot. Batson's work, however, obviously provides an explanation also of those puerperal cases in which thrombosis is limited to cerebral veins and those in which sinuses other than the superior longitudinal are involved.

The occurrence of a spinal lesion in my second case receives its explanation, too, from the hypothesis that fragments are transmitted by way of the vertebral veins if we suppose that thrombosis first took place in the extrathecal veins at the affected level and consequently spread into the spinal veins.

The prophylactic measures which these considerations suggest are obvious. When a patient is suspected of having pelvic thrombosis every precaution should be taken to avoid straining, the binder should not be tight, and the patient should be kept well propped up in bed.

Summary

Thrombosis in the superior longitudinal sinus occurs in the puerperium and after abortion.

The clinical diagnosis depends on signs of raised intracranial pressure and signs of obstruction of superior cerebral veins. Under certain conditions the diagnosis may be made in the presence of only one of these groups of signs.

Clinical accounts are given of three cases which are believed to be of this nature.

It is suggested that a fragment of clot carried up to the superior longitudinal sinus from the pelvic veins by way of the vertebral venous system acts as the nucleus for the clot which forms in the sinus.

All the cases described in this paper were seen at Whipps Cross Hospital, and I am indebted to the medical superintendent, Mr. O. R. M. Kelly, for permission to describe them.

J. H. Levy (*Tri-State med. J.*, 1941, 13, 2642) states that diabetic neuritis, the incidence of which according to different observers ranges from 0.6 to 57.3% of the total number of diabetics, is probably not dependent upon vitamin B. lack. Supplementary or properly organized diet with the vitamin in pure chemical form is therefore not indicated.

ORAL MEDICATION BY SOBISMINOL IN THE TREATMENT OF SYPHILIS

BY

R. C. L. BATCHELOR, M.A., M.B., F.R.C.S.Ed., D.P.H.

MARJORIE MURRELL, M.B., F.R.C.S.Ed.

AND

G. M. THOMSON, M.D., D.P.H.

(From the Edinburgh Corporation and Royal Infirmary
Department of Venereal Diseases)

Towards the end of the era of mercurial therapy in the treatment of syphilis there was entertained and freely expressed a decided preference for the parenteral rather than the oral route of administering the drug. It was insisted that with the oral method there was no uniformity of absorption and that gastro-intestinal disturbance was more often encountered. The prejudice thus established against the oral administration of antisyphilitic remedies still persists. Although there has been no backward swing of the pendulum, an inclination towards further exploration of the possibilities of the oral route has certainly been manifested recently. Nabarro (1941) has strongly advocated the use of ingested stovarsol, a pentavalent organic arsenical, in the treatment of congenital syphilis in infants; and several American publications have described experiences with an orally applied bismuthial—sobisminol—in the treatment of acquired syphilis in adults. The present article deals with a small series of cases treated with sobisminol (sodium bismuthate soluble), "a complex organic bismuth compound the chemical structure of which has not been established."

Methods of Administration Compared

The advantages and disadvantages of the oral treatment of syphilitic infections may here be briefly recapitulated. Only a small proportion of patients fail to become accustomed to "the needle" after the first few injections. Efficient injection technique is attended with very little immediate pain, but when several injections a week are given (e.g., two or three intravenous arsenicals and two intramuscular bismuthials), and especially when the intramuscular injections cause tenderness and stiffness, as occurs with oil-soluble bismuth, then many patients would appreciate a period of relief from "that pincushion feeling." Also, especially in women with fat-infiltrated hips, it may be difficult to prevent the bismuth forming pockets, from which absorption is slow, or seeping back along the needle track to form tender subcutaneous nodules. Moreover, some women are averse to receiving hip injections during a menstrual period. Also, especially at the present time, seafaring men on long voyages may be delayed in reaching a port where injection treatment could be continued, and may find regular visits to V.D. clinics impossible. In these and similar cases a potent drug for oral administration would satisfy a real need in antisyphilitic therapy. In the present emergency an important consideration is the saving of time, and the taking of a drug by mouth exacts but a small fraction of the time required for visits to a clinic or a doctor.

On the other hand an oral medicament may vary in its degree of absorption, and therefore of potency, in different individuals and in the same individual under different conditions—e.g., of bowel activity. The use of this route may cause gastro-intestinal irritation, leading to nausea, anorexia, vomiting, and diarrhoea, with, of course, lessened absorption or enforced cessation of administration. The regular use of an oral medicine, too, depends upon the mentality and co-operation of the patient, and carelessness

and forgetfulness are special attributes of V.D. patients. A simple and easy treatment is regarded as much less important than the injection visit, and may lead to an erroneous impression as to the seriousness of the disease. The major disaster to be avoided is that the patient should come to believe that the control of treatment is within his or her own competence: oral medication tends to propagate this fallacy, and self-treatment by the patient is absolutely inadmissible. All orally administered antisyphilitic remedies should be scheduled at once and be obtainable on prescription only.

The manufacturers state that, given orally, sobisminol is reputed to have an antisyphilitic effect comparable to that produced by other soluble compounds of bismuth given intramuscularly. It is further averred that a daily dose of from six to nine 0.75-gramme capsules (each representing 150 mg. of bismuth) will produce a satisfactory concentration in the blood stream in most patients, and that probably the optimum dose is six capsules a day.

The small series of cases now to be discussed comprised twelve male and three female patients, all of whom were admitted to hospital in order to facilitate close observation.

Sobisminol Treatment: Male Cases

Of the male patients eleven had primary genital chancres and one had a primary chancre of the lower lip. In all cases before starting treatment *Spirochaeta pallida* was demonstrated in serum from the primary lesion and a blood Wassermann test was made. Thereafter treatment with sobisminol was begun and the chancre dressed with saline, serum from it being examined daily for *S. pallida*. The blood Wassermann test was repeated at the end of the course. Immediately the administration of sobisminol orally was stopped intensive routine antisyphilitic treatment with intravenous "914" or stabilarsan and intramuscular bismuth was begun.

Particulars of the eleven primary genital cases are given in Table I.

TABLE I

Case No.	Blood Wassermann at Outset	No. of Capsules per Day	Total No. of Capsules given before Arsenicals Started	<i>S. pallida</i> Absent After	Blood Wassermann at End of Course
1	++	6	42	4 days	+++
2	++	6	38	3 "	+++
3	++	6	54	2 "	+++
4	+	6	67	8 "	+++
5	+	6	66	8 "	=
6	++	9	36	3 "	+++
7	++	9	45	<i>S. pallida</i> present at end of 5 days	+++
8	+	9	51	3 days	+
9	—	9	54	4 "	—
10	—	9	39	4 "	—
11	—	9	39	4 "	—

In the twelfth case dark-field examination of serum showed dead *S. pallida* only, as this patient had been applying antiseptics to the erosion. His wife, however, was admitted to hospital with a lip primary chancre, less well developed, which showed living and active *S. pallida* on dark-field examination. The husband's blood Wassermann reaction was strongly positive. Treatment with six capsules of sobisminol daily was started, and was continued for twelve days, during which time the lesion increased in size and was covered with a crust. On the twelfth day an early macular rash was visible on the trunk; thereupon sobisminol was stopped and intravenous "914" begun.

Commentary.—The average number of days before the dark-field serum tests became free of spirochaetes was 4.2. At the end of the course three cases which at the outset of treatment showed a negative blood Wassermann reaction became seropositive, and in two other cases the intensity

of the blood Wassermann reaction was increased. One patient developed a secondary macular eruption after eleven days of treatment. These last clinical findings may seem to infer that the undoubted antagonistic influence of oral sobisminol on primary syphilis is yet not strong enough to prevent the generalized systemic extension of the disease. Nevertheless it is commonly observed in the routine treatment of early syphilis that a positive blood Wassermann reaction may increase in intensity after each injection of "914" ("provocative" effect), and the first injections may accentuate or accelerate the appearance of an early rash.

Female Cases

Particulars of the three female patients are given in Table II.

TABLE II

Case No.	Blood Wassermann at Outset	No. of Capsules per Day	Total No. of Capsules given before Arsenicals Started	S. pallida Absent After	Blood Wassermann at End of Course	Bismuth Excretion
1	+++	6	108	6 days	+++	11.52 mg. per day after 18 days
2	+++	6	68	3 days (serum from condylomata)	+++	
3	+++	6	88	6 days (serum from condylomata)	+++	12.5 mg. (5th day); 5.04 mg. (10th day); 4.29 mg. (12th day)

Clinical Observations.—The oral sobisminol, given alone, achieved rapid resolution of the syphilitic manifestations, whether primary sore, condylomata lata, or mucous patches. In the first two cases an early examination of the cerebrospinal fluid was carried out, on the twelfth and the sixteenth day respectively, and in both cases all the tests, including the cell count, globulin estimation, Wassermann, and gold sol, were negative. In all three cases the sobisminol was continued after an arsenical (stabilarsan) had been introduced, and altogether totals of 212, 512, and 142 capsules were given. In the first case, an early secondary, the blood Wassermann reaction became negative after only three intravenous injections, each of 0.2 gramme, of stabilarsan. In the second case, a late secondary with condylomata lata, the Wassermann reaction was negative after eight intravenous injections of stabilarsan (2 of 0.15 gramme and 6 of 0.3 gramme), given twice weekly. If any deduction were permissible, it would be that the oral sobisminol had acted as a powerful adjuvant of the injected arsenical.

Toxic Effects

Only two of the male patients complained of any upset. In both cases the symptoms were "indigestion" and nausea, which were relieved by a sedative powder.

Two of the female patients experienced untoward effects before the arsenical injections were started. The first had severe abdominal pains during the fifth night, but they were not accompanied by nausea or diarrhoea. The following day she complained of a sore tongue, but the abdominal pains subsided and the glossitis gradually abated, although the capsules were continued in unredacted dosage. Later there was some soreness of the throat and the fauces were slightly red, but the gums remained healthy. The second patient developed a stomatitis on the eighth day and sobisminol was withheld for one day. Thereafter it was found possible to resume the capsules, although slight gingivitis and blue

discoloration of the gums persisted. This patient received a total of 512 capsules in less than three and a half months. The third patient received 88 capsules before the arsenical was started, and without untoward incident; but after three small intravenous injections of stabilarsan (two of 0.2 gramme and one of 0.1 gramme) she had nausea and vomiting: these symptoms passed off in a few days and the capsules were continued until a total of 142 had been taken.

In general the toxic manifestations were not severe; they were mainly referable to the alimentary system, and sometimes subsided when the drug was continued. There was no evidence of cumulative toxic effects after the drug had been administered every day for many weeks.

Summary and Conclusions

The results are reviewed of the oral exhibition of sobisminol in twelve male and three female cases of early syphilis. Suggestions are made as to the province of sobisminol in antisiphilitic therapy.

Deductions from such a limited experience as is afforded by this small series may not be regarded as acceptable, but the object of this paper is to suggest a sphere of usefulness for oral sobisminol without attempting to draw hard-and-fast conclusions.

Our results do not justify the use of oral sobisminol alone in cases of early syphilis, particularly in wartime, when it is essential to render the patient non-contagious as soon as possible. It would appear, however, that sobisminol can and should have a place in the treatment of the following classes of patients: (1) those who cannot attend regularly for injection therapy—e.g., long-distance seamen; (2) those who are intolerant of arsenic and in whom for any reason injection therapy is contraindicated; (3) those who show persistently positive serological tests in spite of long-continued parenteral treatment: in these cases oral sobisminol might be a logical and valuable alternative to the time-honoured mercury pills. One of us (R. C. L. B.) has in mind a tertiary case in which sobisminol provided a most useful stopgap during a long voyage from the East. This female patient realized that regular visits to the ship doctor might excite comment and inquiry.

We are indebted to Messrs. Eli Lilly and Co. for supplies of their product, Pulvules Sobisminol Mass.

MENTAL HEALTH IN WARTIME

The subject of mental health, states the annual report of the National Council of Mental Hygiene, has received an impetus denied to it in the leisurely times of peace. The war has not so far produced any appreciable increase in nervous disorders, but the great changes in national life are bringing to the fore persons suffering from nervous and emotional reactions. Many such cases are encountered in shelters, rest centres, and first-aid posts. Evacuation has also brought its own problems, especially among nervous and difficult children, the subnormal, epileptics, and neurotics of old standing, and a good deal of emergency psychiatry has become necessary. The Council, now in its eighteenth year, has organized lectures on practical methods of dealing with nervous manifestations under war conditions, has produced a film on the prevention and treatment of fear, has compiled a directory of out-patient clinics for functional mental and nervous disorders, and has given attention to mental testing in the Services, psychological problems among enlisted women, and wartime mental health propaganda, among other subjects. Lord Alness, who has been associated for some time past with the Tavistock Clinic, has accepted the chairmanship of the Council, vacant by the resignation of Mr. Walter Roth, and Dr. H. Crichton-Miller the treasurership.

RADIOGRAPHS AND DISPROPORTION

BY

J. V. O'SULLIVAN, M.D., F.R.C.S., M.R.C.P.,
M.A.O., M.R.C.O.G.*Assistant Obstetric Surgeon, City of London Maternity Hospital
and Queen Mary's Hospital for the East End;
Surgeon, Emergency Medical Service*

WITH AN ADDENDUM

BY

F. M. CRAWSHAW, M.A., M.B., B.Chir., D.M.R.E.

Radiologist, Emergency Medical Service

Disproportion is one of the most worrying abnormalities in midwifery. Particularly is this so in medium and minor degrees of contracted pelvis, in which diminished reserve capacity of the pelvis is so difficult to assess. Marked overlap, of course, renders the diagnosis easy. It is in the type of case usually treated by a test labour that radiographs are of the greatest importance. The method employed in this series of cases is simple, and can be carried out by any radiologist using the ordinary apparatus.

A New Method of Estimating Disproportion

Dr. J. W. McLaren, radiologist to Queen Mary's Hospital for the East End, first drew my attention to a method which I was soon convinced was of great value as a visual aid in test labour cases. I conduct no test labour now without taking special films of the case. At the outbreak of war the Lyle Maternity Wing of Queen Mary's Hospital was closed and I continued the method at the Kingston County Hospital, where Dr. Crawshaw, the E.M.S. radiologist, has given every co-operation and has further developed the method. All cases analysed in this paper were cases of disproportion. The diagonal conjugates varied between $3\frac{1}{2}$ and $4\frac{1}{2}$ inches, the great majority lying between 4 and $4\frac{1}{2}$ inches. The foetal heads in all cases remained above the brim at ante-natal visits and could not be "pushed in" by the usual manoeuvre of pressure downwards and backwards into the pelvis or by sitting the patient up. Overlap was present in several cases, as shown by ordinary palpation and by Munro Kerr's method. All these women were examined weekly towards the end of pregnancy, and on each occasion attempts to make the head engage failed.

I would like to add one clinical finding most helpful in giving an opinion; it is that in those cases in which the position remained constant—i.e., L.O.A. or R.O.A. at the last three or four visits—the patients delivered themselves spontaneously.

Patients were radiographed in the last two weeks of pregnancy, and the usual method of calculating the expectant date (adding seven days to the L.M.P. and going forward nine months) was adopted. Some of the radiographs were taken when the patient was actually in the first stage of labour. Dr. Crawshaw gives in the Addendum the technical details of the method used in taking the radiographs. I would like, however, to emphasize that the antero-posterior film should be large enough to show the whole foetus and the brim of the pelvis. This will enable the radiologist to exclude abnormalities in the foetus; also to show the lie, position, presentation, and degree of flexion of the head, and the relation of the head to the conjugate diameter of the brim. If the head lies centrally the antero-posterior diameter of the brim and of the head are magnified proportionately when a true lateral film is taken. If

the head is lying obliquely at the brim an oblique diameter is of course projected, and this diameter is always greater than the biparietal.

Interpreting the Films

It will be remembered that the foetus during its progress through the pelvis traverses the obstetrical pelvic axis. This axis at its commencement corresponds with the first part of the curve of Carus and may be represented at the brim by a line drawn upwards at right angles to the mid-point of the plane of the brim. Making use of this knowledge, I found the best way to read the lateral radiographs was to draw a line on the films between the promontory of the sacrum and the upper posterior margin of the symphysis pubis, and from each extremity of this antero-posterior diameter of the brim to erect perpendicular lines, thus forming the sides of a "box" (see diagram). This plan has

Diagram showing perpendicular lines erected at extremities of true conjugate to form sides of box.

been followed in the reading of all the films, and wherever the foetal head fitted easily between the perpendicular lines it could be safely assumed that it would go through the brim. The erection of these perpendicular lines makes the reading of the films simple and accurate. It is self-evident that if the biparietal diameter does not fit into the "box" no other diameter can, and Caesarean section is advisable.

In our opinion a good lateral film is the radiological counterpart of Munro Kerr's clinical method. Originally we took the lateral films with the patient lying on her side on the x-ray table, being careful that the thighs were not flexed sufficiently to obscure the top of the symphysis. Recently, however, Dr. Crawshaw has taken the lateral view with the patient standing up and leaning forward with her hands grasping the back of a chair. It will be recalled that this is the natural position for a patient to assume when she is seized with a pain while walking about during the first stage of labour. This position brings the uterus, and with it the foetus, at right angles to the "position of entry."

Results

I have analysed 102 cases over the last three years and find that the radiologist's report was wrong in only six instances. In three of these the report said the head would not pass, and it moulded through, with the aid of forceps, in one case; in one the report said the head would pass, and it did not; while in the remaining two the report said the heads might pass, and Caesarean section was necessary.

I have had cases in which, though the head could not be pushed in clinically, the film showed that it would pass. In one case I was so doubtful that a week after the expectant date I took the patient to the theatre for examination under anaesthesia and probably for Caesarean section. Under the anaesthetic the head would partially enter the brim. In view of this and the definite radiological report I ruptured the membranes with a Drew Smythe catheter, and spontaneous delivery of a living child followed during the next twenty-four hours. There were other very doubtful cases in which this simple radiological aid was of the greatest help to me.

I am convinced that this method is of great value in cases of disproportion. The films should be taken as near the expectant date as possible if the fullest aid is to be obtained from them.

ADDENDUM

The method of estimating disproportion described in this paper depends upon the fact that if any diameter of the head and the true conjugate of the pelvis are equidistant from the film the magnification of these is the same. Hence it can only be of use in vertex presentations with the head central in the pelvis. It gives no information in any other presentation or in cases of outlet contraction. In spite of these limitations it is of considerable value to the obstetrician, because it is in the true conjugate diameter that disproportion is most often encountered.

Examination of the antero-posterior and lateral views of the pelvis enables the radiologist to see if the head is lying transversely or obliquely: as already stated, if the foetal head lies obliquely in the pelvis a diameter larger than the biparietal is projected. In a high percentage of cases clinically suspected of disproportion the lateral radiograph shows that there is a large clearance between the size of the foetal skull and the true conjugate, and disproportion can be excluded. The question of what relation between the foetal skull and the true conjugate constitutes disproportion is a real difficulty. Mere direct comparison of the size of the bony parts is clearly not sufficient, because there are always unknown factors—e.g., the degree of moulding and the thickness of the soft parts—to be considered. The radiologist must therefore make his rules of interpretation from experience of what happens in labour.

In the above series of cases the rule has been used that where the biparietal diameter is greater than the true conjugate disproportion exists; where it is equal to the true conjugate the head will only go through with moulding; and where it is less than the true conjugate no difficulty from disproportion need be anticipated. It may be that this rule will have to be altered as a result of further experience, but enough has been learnt to show that it is not far from the truth. In those cases in which the head is lying obliquely and in which the oblique diameter of the skull projected is greater than the true conjugate it is not possible to be certain whether disproportion exists or not.

As to the actual radiography, the lateral films may be taken with the patient lying on her side or, if a vertical Potter-Bucky is available, standing with the arms supported on the back of a chair. The hips should not be flexed, as this may cause the shadow of the symphysis to be hidden by the shadows of the femora. To be of use the film should not be far from a true lateral as judged by the superimposition of the shadows of the femoral heads.

Our grateful thanks are due to Dr. McLaren (who would have collaborated with us but for his absence on active service). Our thanks are also due to Mr. Kidd, superintendent of Kingston County Hospital; to Mr. A. McAlister of Queen Mary's Hospital, Stratford; and to the resident and the radiological staffs of the two hospitals.

SULPHANILAMIDE IN LOCAL TREATMENT OF SKIN INFECTIONS

BY

A. G. MARSHALL, M.B., B.Chir.

Flight Lieutenant, R.A.F.V.R.

Localized infections of the skin such as sycosis and impetigo contagiosa have been found difficult to heal, especially when established for some time. In the Services, although these conditions are not common, the time factor and the prevention of cross-infection combine to make the problem an important one. Older methods of treatment, such as the application of ointments after bathing the lesions, are tedious and in many cases ineffective. Gentian-violet paint was not used in the following series of cases. The recent satisfactory reports of the treatment of wounds by the local application of sulphanilamide powder suggested the extension of this method to such conditions. The results have been most gratifying.

The usefulness of sulphanilamide therapy in skin diseases has been the subject of much discussion, and its value is stated by Smith (1940) to be far from understood. He reports good results in the local application of solutions and ointments to ulcers and infected burns and refers to the advantages of economy and atoxicity. Jaeger (1936) and Merz (1937) have treated skin lesions with the drugs given orally, and locally as solutions in water and glycerin: the latter applied his methods to impetigo. Buchanan (1940) points out the value of crushed tablets of sulphapyridine as a dressing for a pneumococcal ulcer, a treatment which is often of use in varicose ulceration. Under present war conditions I have been able to trace only one author who specifically mentions the use of the powder for infections of the skin: MacKenna (1940) employed it under a dressing of zinc paste for impetigo, and stated that it is often successful.

Method

The patients were treated in hospital as ambulant but isolated cases. The scabs were bathed off three or four times daily with a warm 2% solution of sodium bicarbonate. The sulphanilamide powder (streptocide) was applied direct to the raw surface, where it sticks well, and was left with no dressing. The treatment was usually carried out by the patient after the first few times, and he used more powder when required. It was of course essential to continue regular shaving in the healthy areas, and the hair was clipped short elsewhere. Frequent shampoos were given. In cases with thick masses of exudate which did not separate easily a gauze pad soaked in liquid paraffin was applied for twelve hours, and the treatment then continued, the old exudate separating readily with this application. Other oily dressings were rigidly avoided, as they were found to spread the infection. In certain cases, described below, ascorbic acid was prescribed by mouth, starting with 500 mg. daily, the dose, after saturation, being reduced progressively to 50 mg. daily.

Results

All the cases had already been treated with bathing and ointments. There was immediate and decided improvement after the application of sulphanilamide powder. The surrounding inflammation and the exudation rapidly decreased, and in three days the lesions were sterile and remained so. Case 4 (see below) was at first treated with sulphanilamide ointment, but after a week the lesions had not become sterile nor apparently had they improved. It is therefore suggested that a high concentration is necessary to destroy the staphylococcus. This is unlikely to

occur to an adequate degree when the drug is given by mouth only. There was much drying of the surface, but it was found better to ignore this and to maintain sterility. In the old-standing cases healing of the deep granulating areas was slow, and in these ascorbic acid was given. In comparison with similar cases without this addition healing was more rapid. Further stimulation of healing by ray treatment was not found necessary in any of this series. Sulphapyridine and sulphathiazole powders were not used: results were satisfactory with sulphanilamide powder, which was more readily obtainable.

Illustrative Cases

Case 1.—This patient had severe staphylococcal infection of a large part of the face, which had been treated for seven days before admission with acriflavine dressings and then with eau d'Alibour. As the condition became much worse the areas were cleaned with olive oil, and ung. hydrarg. ammon. dil. was applied. There still being no improvement, the patient was admitted to hospital and treated with sulphanilamide powder. Three days later the areas were clean and almost sterile. Healing was complete ten days after admission.

Case 2.—This case was complicated by submaxillary suppurative adenitis, the organism being *Staphylococcus albus*. There were large infected areas on the lips and chin, and the patient had been treated with bathing and ointments for ten days. The abscess was drained and local sulphanilamide treatment for the face started. He would have been fit for discharge after twelve days had he not developed measles shortly after admission.

Case 3.—This patient first began to have suppurative lesions of the face in February, 1940. He had been treated with bathing, oils, and ointments, but states that he was never entirely free. His left eye began to be painful in September, 1940, and the right eye soon followed suit. He was admitted on November 1 with severe ulceration over the upper lip and chin, with a hard exudate and deep fissures. Both eyes showed purulent blepharitis. After bathing and application of the powder the inflammation around the lesions decreased, and the eyes, for which boric lotion was used, had healed. The central parts of the lesions, which were deeply crusted with adherent exudate, were cleared with packs of liquid paraffin. Further powder was applied, and shaving or close clipping of the beard was continued throughout. On November 19 the whole area was clean and so nearly healed that the man was returned to duty. In this case ascorbic acid was given from the time of admission.

Case 4.—This was an early case of impetigo contagiosa that had been treated with ointments for four days. The affected areas were bathed and streptocide ointment was applied. After three days the lesions gave a massive growth of staphylococci: this was maintained for a week. On the seventh day treatment was changed to the powder, following which the lesions rapidly became sterile and remained so. After seven days' slow progress ascorbic acid was given; healing was then rapid and the patient was discharged five days later.

Summary

A method of treating local skin infections with sulphanilamide powder is described.

Progress was rapid in comparison with older methods.

Ascorbic acid by mouth and ray treatment are suggested for accelerating healing after the infection has been cured.

My thanks are due to Wing Commander J. M. A. Costello for permission to publish these cases and for his advice and interest.

Medical Memoranda

Traumatic Asphyxia

It would seem that traumatic asphyxia is rare enough to warrant a typical case being put on record.

CASE REPORT

An errand-boy aged 14, after being knocked off his bicycle by a lorry, was admitted with bruising of the left hip and cuts around both knees. The most striking features, however, were his dusky complexion, his cyanosed lips, and the numerous tiny petechial haemorrhages on his face, conjunctivae, neck, and upper part of chest to the level of the second rib; they were more prominent on the left side, and it was observed that the area of skin underlying his collar and braces was unaffected. He complained bitterly of inability to swallow and of difficulty in breathing: although his respiration rate was not much increased, the depth was irregular and less than normal. He had no pain or tenderness in the chest, and physical signs were normal. His condition at the time was that of shock and asphyxia. His minor injuries were duly treated, and morphine and warmth soon relieved the shock; nasal oxygen was given for the asphyxia with the patient in a sitting position.

Two hours after admission his general condition was slightly better, though the dyspnoea and cyanosis showed no improvement; he was still unable to swallow. The petechiae in the skin were more pronounced, while those in the conjunctivae were beginning to coalesce. Oedema of the eyelids, face, and lips was noticed at this time. The dysphagia and cyanosis were slowly passing off and the breathing was a little easier twelve hours after admission. There was no white to be seen in the eyes at all. Physical signs in the chest were normal, and rib tenderness was absent. The oedema and petechial rash were rapidly subsiding twenty-four hours later, the oxygen being discontinued after a period of thirty-six hours.

Early in convalescence his chest was radiographed, but showed no abnormality. Except for a small residual quantity of blood in the conjunctivae, complete recovery had taken place, and the patient was discharged three weeks after the accident. He constantly affirmed that he did not lose consciousness, and that the lorry did not run over or even touch any part of his head, chest, or abdomen.

DISCUSSION

Cause.—It seems reasonably certain that asphyxia is due to a sudden distension of the superior vena cava and its tributaries by a sudden compression of either the thoracic or the abdominal veins. The sudden distension causes a capillary paralysis with or without rupture and extravasation of blood. The areas draining via the jugulars into the innominate veins are affected, as these vessels are deficient of valves: the same is true of the subclavian veins, when the arms also show the characteristic changes. The lack of cerebral symptoms is presumably due to the baffling effect of the large blood sinuses at the base of the brain.

Diagnosis.—The characteristic picture is seen in the case described above. The extremely clear line of demarcation of the dusky blue areas soon to be covered with petechiae calls for special attention. The upper chest, neck, shoulders, and face are the parts affected. The dyspnoea and dysphagia are typical.

Treatment.—Morphine and warmth soon relieve the patient's apprehension, but the administration of oxygen brings ease almost immediately. The latter should be continued until the patient fails to derive benefit from it.

Prognosis.—Traumatic asphyxia itself does not terminate in death. The outlook as to life is good in all cases; but as to sight the prognosis should be guarded, for atrophy of the optic nerve has been recorded.

I wish to thank Dr. J. M. Christie for permission to publish this case and for his helpful criticism.

Reviews

RADIOGRAPHY OF SILICOSIS

An X-Ray Atlas of Silicosis. By Arthur J. Amor, M.D., M.Sc. Translation of the legends into French by Robert E. Horne, M.A. With a foreword by Sir Wilson Jameson, M.D., F.R.C.P. (30s. net.) Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall, Ltd. 1941.

In compiling *An X-Ray Atlas of Silicosis* Dr. Arthur J. Amor aims at setting out the essential features of silicosis for senior students, factory surgeons, and others working in industrial diseases. The book consists of 28 pages of text, followed by the atlas itself of 72 plates. An excellent introductory chapter outlines the problem and discusses the aetiology of silicosis. There follows an account of the pathology of the condition and then of the radiological manifestations. These are well described, although exception may be taken to the statement that "if a calcification of the hilum glands occurs, that is almost specific of silicosis." An interesting point brought out by the author is that cavitation is not commonly seen when tuberculosis supervenes on silicosis, and that other signs, such as fluffy outline of the nodules and coalescence into large opacities, must be relied upon in diagnosing this complication. The problem is made more difficult by the large number of cases with negative sputum. The text finishes with two short chapters on the clinical and prognostic aspects.

The atlas proper is divided into three sections. The first section deals with the various stages of silicosis. These 37 radiographs are well chosen, and give a clear picture of the evolution of the disease from a slight reticular fibrosis, through the stages of nodulation, coalescence, and development of silico-tuberculosis. The second section is devoted to a comparison of the appearances of silicosis as it is seen in the various industries in this country. The 24 plates in this section make an admirable record of the variations met with; of particular interest are the four radiographs illustrating the evolution of the condition in a haematite miner, a tin-miner, a potter, and a sand-blaster. This section ends with pictures of such complications as gross calcification, bullous emphysema, and pneumothorax. The last section deals with the differential diagnosis, and includes samples of miliary tuberculosis, carcinomatosis, and asbestosis. If one were seeking to find a fault it would be that the subject of asbestosis is not discussed in greater detail.

The author is to be congratulated on producing a monograph of great merit, and one that is warmly to be recommended to those who are interested in the subject.

CUSHING'S LIFE OF OSLER

The Life of Sir William Osler. By Harvey Cushing. Complete in one volume. (Pp. 1,417. 21s. net.) London, New York, Toronto: Oxford University Press. 1940.

"Some men command admiration by their intellectual gifts, others, perhaps fewer, attract by the magnetic charm of their personality. When these characteristics are combined in the same individual his influence is irresistible. Such a man was William Osler." So wrote Sir Walter Langdon-Brown in his biographical note for a new edition of Osler's famous collection of addresses entitled *Aequanimitas*. We quote these apt words in making known to our readers the republication of another favourite book, Harvey Cushing's *Life of Sir William Osler*, which first appeared in 1925 in two volumes, within four and a half years of the beloved physician's death. Cushing was Osler's pupil, colleague, and friend. The book was reviewed at length in these columns by another friend—Sir Humphry Rolleston—who

described it as a suitable memorial to "a wonderful personality, the like of whom we shall not look upon again." It won the Pulitzer prize for biography in the year of publication and has since continued to attract thousands of new readers. This one-volume unabridged edition makes it possible for many more to have the book "for keeps." Drs. J. F. Fulton and W. W. Francis have written a short foreword in which they recall a few facts about the distinguished author of the biography. Harvey Cushing, they say, "has now joined the Oslerian ranks of those who, though no longer with us, still shape our lives." During his days in Baltimore in the surgical service of William Halsted at Johns Hopkins, Cushing came into close contact with Osler, and for some years he lived next door. In Sir William's phrase, he became a "latch-keyer," and we now learn that many of the anonymous allusions in the text of this biography to "those privileged neighbours" have reference to Cushing himself; the two men were on terms of the closest intimacy for nearly twenty-five years. "Osler's love of books and his almost phenomenal capacity for work stirred in Cushing a whole-hearted admiration that made him immediately respond when Lady Osler invited him to prepare her husband's *Life*."

All but eleven of the original forty-seven illustrations have had to be omitted from the new edition, but apart from this and minor corrections there are no changes. It has been well printed in the United States for the Oxford University Press of New York, and is published in this country by Sir Humphrey Milford as one of the productions of the Oxford University Press. Many will be grateful for this pious enterprise and think the result wonderfully good value for a guinea.

A TEXTBOOK OF SKIN DISEASES

Essentials of Dermatology. By Norman Tobias, M.D. (Pp. 497; illustrated. 28s.) Philadelphia, London, Montreal: J. B. Lippincott Company. 1941.

This work emanates from the University of St. Louis, where the author is the senior instructor in dermatology under a veteran professor, to whom it is dedicated on the occasion of his eighty-second birthday. Is there no professional age limit at St. Louis? The book bears a strong resemblance to many other American textbooks of dermatology. It is quite sound and devoid of startling features. It is well illustrated, mostly by photographs, but there are no coloured plates. The chief criticism we have to make on it is that the author has attempted to include too many rare disorders and has not quite rationed his space in accordance with the relative importance of the conditions dealt with. But he has reduced to a minimum histological descriptions and theoretical considerations in view of the fact that the volume is intended for students, and he has done his best to discuss the various diseases from the standpoint of internal medicine. This is a common statement in prefaces to dermatological textbooks, and the impression is often given that almost all of dermatological conditions are merely the external expression of internal derangement. No doubt there are diseases of which this is undoubtedly true. The rashes of the exanthemata and drug eruptions are salient examples. But to a large extent the skin is an independent organ and develops independent diseases which in their turn affect the remainder of the patient. This aspect of dermatology has to a large degree been neglected and deserves more attention. However, this is not the place for an essay on it. The preface also throws a light on the real reasons that make doctors write books. It is, of course, well known that no member of the profession ever bursts into print in order to demonstrate to the world that he is an authority on the subject and ought to be consulted thereon, for this would be a form of advertisement and

therefore reprehensible in the extreme; but it is not often divulged that the compilation of a textbook is undertaken in order that the author may himself acquire a better knowledge of his subject. Dr. Tobias admits this very creditable motive (which has no doubt often actuated others), and we may hope that he has been successful in improving himself as a dermatologist.

MEDICAL PROBLEMS OF WAR

Wartime Health and Democracy. By Hugh Clegg, M.A., M.B., M.R.C.P. (Pp. 64. 1s. net.) London: J. M. Dent and Sons, Ltd. 1941.

For the information of the general public Dr. Clegg has written a straightforward non-technical account of the ways in which the medical profession prepared for and has met the problems created by the war. In the past, wars were often brought to an abrupt conclusion by epidemic diseases, and a cynic might remark that while physics and chemistry have increased man's homicidal capacity, the biological sciences have enabled him to exercise it without so much interference from the superior killing power of germs. As things are, however, the medical profession may be proud of their contribution, as here detailed, to the mitigation of inevitable suffering. The facts about food are clearly set forth, classified under foods for warmth and energy, foods for building and repair, and protective foods. Attention is drawn to the shortage of animal proteins, and it might be added that to make this good by low-grade vegetable proteins involves a great increase in the total bulk of food consumed, as shown by McCance and Widdowson. The verminous condition of many evacuated children has come as a real shock and surprise to the community, and Dr. Clegg is of opinion that the reports of a steady decline in the infestation of school children since 1915 did not represent the true state of affairs, which calls for rigid investigation and drastic remedies. He points out the real danger of the reintroduction of typhus into this country through lice. Many of the other difficulties with evacuated children he refers to the severance from parents and familiar surroundings, and calls attention to the remarkable conclusion of the psychologists that the mental strain is greater among the children sent to the reception areas than among those left behind in the bombed cities.

Dr. Clegg's remarks on the post-war planning of medicine are timely and well worth consideration. He is clear that the individual doctor will have to work in closer co-operation with his fellow doctors, but whatever the final outcome the relationship between the family doctor and his patient must not be impaired by officious intervention; bureaucratic medicine is not democratic medicine. "Like other workers the doctor wants security so that he can work unhampered by economic fear; but let us hope that he does not get this by handing himself over to a heavily paternal State." Here in this little book is much wisdom in a small compass.

W. L.-B.

Notes on Books

The book entitled *Anus-Rectum-Sigmoid Colon: Diagnosis and Treatment*, by Dr. HARRY E. BACON of Philadelphia, appeared first in 1938 and was welcomed in these columns as an encyclopaedia for the proctologist, excellently systematized, readable, beautifully printed, and profusely illustrated. It has already been translated into Spanish and Portuguese, and a second edition is now published by the J. B. Lippincott Company at 50s. The author has included descriptions of new operative procedures for rectal prolapse, and for haemorrhoids, both external and internal, and he pays much attention to the means for avoiding post-operative pain. A method by which the dosage of lumbar analgesia can be calibrated in ano-rectal

surgery is described; also a means for controlling blood pressure during spinal analgesia. There are other additions too numerous to mention here, but it may be noted that almost every chapter is now wound up with a summary of the procedure of choice, so that the reader in need of practical guidance may come quickly to the point.

The new edition of Dr. W. A. BREND's *Handbook of Medical Jurisprudence and Toxicology* has been revised throughout and partly rewritten, especially the chapter on medical evidence. The author has been impressed by the great increase during the last two decades in the demands made by the courts for medical evidence, and by the unhappily large number of general practitioners who come to court with inadequate preparation and little knowledge of what the procedure requires of them. He has therefore paid special attention to the needs of the occasional medical witness. It would have been useful if he had said more about the fees which may be paid to witnesses; he gives only those allowed by the Coroners Act, 1926. His book contains more legal information than most similar works, and this is selected with a view to giving practical help to the doctor. Dr. Brend deals particularly fully with the traumatic neuroses—a subject of which he has special knowledge. Nearly half the book is devoted to poisons. The volume is a neat pocket size, and the print, though somewhat small, is easily legible. It is published by Charles Griffin and Co. at 10s. 6d.

MR. MAURICE WHITTING's book *Ophthalmic Nursing*, which has been favourably reviewed in these columns, now appears in a third edition (J. and A. Churchill, 6s.). It remains a very practical work, based for the most part on the well-tried methods of nursing at Moorfields Eye Hospital. The author covers a wide field clearly and concisely, and preserves a due sense of proportion. The application of treatment by the sulphonamide drugs to diseases of the eye is indicated in this edition, and there is a new short section on gas burns of the conjunctiva and eyeball. This small book should prove useful not only to the nurses for whom it was written, but also to medical students and house-surgeons, and to practitioners having but slight acquaintance with a specialized branch of nursing.

Modern Marriage: A Handbook for Men, by Dr. PAUL POPENOE, is a book to pick out from the many of its kind. It is paternal and persuasive in tone, but not pontifical. Straightforward advice is given, based on statements of biological facts and on statistics, mostly Californian. It is neither sentimental nor aridly scientific, and is attractively practical. The importance of emotional maturity for marriage, and the fact that wedded life should be a continuous development in the dynamic experience of living, are wisely emphasized; so is the value of premarital examination. The format is pleasant and the style clear. The book should certainly be useful as a gift to the young "college man." It is published by the Macmillan Company at 8s. 6d., or \$2.50.

Little more than a year ago we commended Dr. BERNARD J. COMROE's *Arthritis and Allied Conditions* to all general practitioners, and especially to physicians interested in joint diseases. It is a book particularly strong on treatment, and deals very fully and clearly with physical methods and the prevention of deformity. The demand for this work has been so great in America that a second edition now appears (Henry Kimpton, 42s.). The author has rewritten much of the text and added several new chapters, notable among these being a discussion of the sulphonamides, and there are forty new photographic illustrations. It will be observed that the price is high, which is a pity, because general practitioners would find the book valuable in the management of conditions that are all too common.

No. 3 of volume IX of the *Bulletin of the Health Organisation of the League of Nations* is obtainable in this country through Allen and Unwin, Ltd., price 4s. The contents include an account of anti-epidemic work in China in 1939; a critical review of the preventive vaccination of dogs against rabies, by Dr. R. Gautier of the Health Section of the League Secretariat; a paper on nutritional research in the Union of South Africa by Dr. E. H. Cluver; and three papers on the rice problem, one of them by Dr. W. R. Aykroyd, who deals comprehensively with the poor rice-eater's diet.

Preparations and Appliances

METAL GUIDES FOR RUBBER CATHETERS FOR USE IN REPAIRING RUPTURED URETHRA

Mr. H. P. WINSBURY-WHITE, F.R.C.S., writes:

Each guide differs from a metal catheter in the two essentials that in the former the tip screws on and off and the curve is more pronounced.

The length of each guide is such that both ends of a rubber catheter passed along its lumen can project from the two ends at the same time. This feature is essential in certain circumstances. The guides have been made to take the four following sizes (French scale) of rubber catheter: 22, 18, 14, 10. The rubber catheters supplied, not having funnel ends, will readily pass right through the guides. The range of sizes meets the requirements with regard to the different ages of the patients. The curves and lengths of the instruments have been varied in relation to their size (Figs. 1 to 4). These guides are serviceable equally in repairing the two principal types of urethral rupture:

1. Associated with fractured pelvis, in which the urethra is torn across on the proximal side of the triangular ligament (Fig. 8).

2. Resulting from falling astride an object, in which the urethra is torn across on the distal side of the triangular ligament.

In dealing with No. 1, after adequate treatment of shock and haemorrhage, surgical intervention will be necessary for at least the following purposes: to approximate and maintain in apposition the divided ends of the urethra; to provide drainage for the bladder and the prevesical space.

Because of the ordeal through which the patient has already passed, the surgeon before he takes up his knife will wisely make what preparations he can to assure that the purposes of the operation will be fulfilled as rapidly as possible. The gap

between the severed ends of the urethra may be of several inches, but complete apposition of the two segments can be established by employing gentle traction through a self-retaining catheter which has been adapted for this purpose and passed along the whole length of the urethra so as to bridge the gap between the torn ends. There are several variations in the use of the catheter guide in repairing the first type of injury:

Pass a metal guide from the external urinary meatus into the prevesical space; if with the forefinger in the internal segment of the urethra, the guide can be directed into the proximal segment of the urethra,

well and good; but if this manipulation does not succeed a larger metal catheter guide can be passed in a retrograde manner from the bladder into the prevesical space. The tip of the proximal instrument is then unscrewed so that the tip of the other can engage its open end. The distal instrument can now be drawn into the bladder, projected through the suprapubic wound, the tip unscrewed, and a properly prepared self-retaining catheter threaded along the lumen of the guide (Fig. 9), which is then withdrawn, leaving the catheter in position. In the absence of a specially constructed self-retaining catheter—which will in due course be available—a rubber collar of the dimensions of a half-crown is threaded on to the catheter and fitted snugly to the neck of any pattern of suprapubic self-retaining tube or catheter of the appropriate size. The collar must be firmly fixed to the catheter by two silkworm-gut threads which are knotted and left long and drawn out through the suprapubic wound. It means of a silkworm-gut thread are afterwards fitted to the skin near to the wound edge, and in due course used for withdrawing the catheter through the suprapubic wound. If the catheter employed has a funnel-shaped outer end, this should be cut obliquely so that it will pass smoothly along the lumen of the metal guide.

Alternatively a Malecot or a de Pezzer catheter may be used instead of the external urinary meatus on a curved stylet may be passed from the external urinary meatus and thus used instead of the distal metal guide. When this has entered the bladder, and while the stylet is still in the catheter,

Figures 1 to 4.—The four different sizes of metal catheter guides fitted with rubber collar.

1. With tip unscrewed and bearing self-retaining catheter size 22 F. fitted with rubber collar.
2. With tip unscrewed and threaded with rubber catheter size 18.
- 3 & 4. The two smallest sizes threaded with sizes 14 and 10 F. rubber catheters.
5. An ordinary metal catheter for contrast with the curves of the metal guides.
6. A self-retaining catheter fitted with rubber collar.
7. A self-retaining catheter specially constructed with a reinforced neck, for traction.
8. A sagittal section of pelvis showing ruptured urethra above triangular ligament.
9. Urethral segments brought into alignment with metal catheter guide threaded with self-retaining catheter ready to be brought into position.

vesical end of the latter is projected through the suprapubic wound so that the rubber disk and silk-worm-gut sutures may be placed in position.

Yet another method is the following: Cut obliquely the outer end of a suitably prepared self-retaining catheter and pass it in a retrograde manner into the prevesical space, where it can then be threaded into the catheter guide which has been passed into the same locality from the external urinary meatus.

Whichever method of passing the catheter has been employed, before the patient leaves the table three longitudinal strips of elastoplast are fixed to the catheter immediately distal to the external urinary meatus, one on the dorsal and one on each lateral aspect. Through these, gentle traction is applied by means of a light weight and a pulley after raising the foot of the bed. By arranging the adhesive on the catheter in the way described several inches of the latter are left free, so that drainage can be instituted in a convenient manner. Ten days of such traction should result in the proximal part of the urethra being fixed in its proper position, so that at the end of this period the catheter may be safely withdrawn, in the manner previously indicated. When the tear through the posterior urethra is incomplete, traction on a self-retaining catheter is

unnecessary, but it is wise to have an indwelling rubber catheter in position for seven days to encourage healing with as little encroachment on the lumen as possible. If an obstruction prevents the passage of the rubber catheter the difficulty may possibly be overcome by passing a metal guide from the external urinary meatus into the bladder. With the tip of the guide projecting from the suprapubic wound the tip of the catheter is seized and held as the guide is withdrawn.

In dealing with a rupture of the urethra in front of the triangular ligament, after opening the bladder suprapubically and exposing the urethral tear through a perineal incision a metal guide is passed in a retrograde manner from the internal urinary meatus till it presents in the perineum. A rubber catheter is then passed from the external urinary meatus into the perineal incision, where it is made to engage the metal guide from which the tip has been removed. Then the guide is withdrawn and the repair carried out over the catheter. When this is accomplished I prefer to withdraw the catheter, for I am of the opinion that an indwelling catheter is not only unnecessary in the presence of the suprapubic drainage which has been provided, but is harmful to the suture line by encouraging sepsis.

A NEW DIRECTOR FOR THE INSERTION OF SMITH-PETERSEN NAILS

MR. JAMES PATRICK, F.R.C.S., orthopaedic surgeon, Glasgow Royal Infirmary, writes:

The principle of using a protractor type of director to estimate the correct line of insertion of the guide-wire along the neck of the femur is well known. The instrument described here was devised with the object of simplifying the construction and assembly of the apparatus and so reducing its cost.

The instrument consists of a sector-shaped piece of metal in which slots are cut lying along the radii of the sector (Fig. 1). On the edge of the circumference is fixed a strip of metal at right angles to the sector plate. On one side of this strip is a series of holes just large enough to take the guide-wire and corresponding in position to the slots. A guide-wire passed through any one of these holes lies exactly over the corresponding slot and enters a

horizontally and the locking screw tightened; an antero-posterior radiograph is then taken (Fig. 2). Should the x-ray film show that the wire is not central a straight line drawn from the centre of the head through the apex of the instrument will lie along one of the slots. This slot is noted and a second guide-wire introduced through the appropriate hole and pushed up along the femoral neck. The first wire is then removed, leaving the second wire in the required line so far as the antero-posterior view is concerned. This wire, of course, may be pointing too far forwards or too far back.

Next the director is removed and rethreaded with the wire along the hollow rod. The instrument is now rotated so that it lies in the vertical plane, and a lateral radiograph is taken (Fig. 2). The appropriate slot in line with the central axis is

FIG. 1.—The director (half-scale).

FIG. 2.—Diagram to show appearance in A-P. and lateral radiograph respectively: central axis marked by dotted line shows which slot the second guide-wire must follow.

space between the main sector plate and a small plate fixed near the apex of the instrument. This latter guides the wire so that it crosses exactly over the apex of the instrument.

On the other aspect of the instrument is a hollow rod fixed so as to lie along the central radius. This rod will allow a guide-wire to pass along it, and there is a locking screw to grip the wire.

In the operation an incision is made over the greater trochanter and the bone exposed. The ridge across the base of the trochanter to which the vastus lateralis is attached is identified and a small hole is made in the cortex about one inch below the ridge. A guide-wire is then inserted as near as can be judged along the central axis of the neck of the femur and the director is threaded on to the wire along the hollow rod. The instrument is adjusted

estimated as before and a wire passed along the neck through the corresponding hole in the director. The other wire is then removed, leaving the final wire in the correct position ready for the insertion of the Smith-Petersen nail. The two holes on the edge of the sector plate of the instrument leave no doubt as to which is anterior or posterior in the lateral x-ray film. Should one hole be inadvertently covered by a metal instrument the other hole will still be visible.

I have used this instrument for the past eighteen months, and so far as the mechanical aspect of the Smith-Petersen operation is concerned it appears to have entirely solved the difficulty of placing the nail in the exact direction desired.

The manufacture of the instrument is in the hands of Down Bros., Ltd.

GAS INJURIES TO THE LUNGS

Faced as we are with the possibility that once again poisonous gases may be used as weapons of warfare, there should be no need to stress the importance of the injuries to the lungs that may result. While many gases and vapours are extremely toxic, it would be wrong to assume that all such gases will necessarily affect the lungs materially. The inhalation of arseniuretted hydrogen, for instance, with its intense haemolytic effect on the erythrocytes; of carbon monoxide, which combines with haemoglobin and so interferes with oxygen transport by the blood; of chlorinated hydrocarbons, which produce intense degenerative changes in the liver and kidneys, may cause death without changes of any significance in the respiratory organs. There is, however, a large group of poisonous gases which includes not only chlorine, phosgene, and chloropicrin, which figured so largely in the last war, but also such gases as ammonia, sulphur dioxide, and the so-called nitrous fumes or higher oxides of nitrogen. These gases have this feature in common, that they are all capable of causing acute pulmonary oedema, and though they may cause in addition inflammatory and necrotic changes in the mucous membrane of the trachea and bronchial tubes, as well as some degree of bronchial spasm, it is in the oedema that the real danger lies, with the threat of death from sheer asphyxia. On the whole it is those gases which have the highest sensory irritant power—for example, ammonia, chlorine, or chloropicrin—which are most liable to affect the bronchial tubes; while those such as phosgene or nitrous fumes, whose sensory irritant power is less, can cause death from pulmonary oedema with but trifling inflammation of the bronchi or bronchioles. The main site of action of these gases is therefore the alveoli of the lung.

Experience in the last war showed that with the development of the oedema two types of case can be distinguished: the one whose suffused and deeply cyanotic facies and distended veins in the neck show that anoxaemia is accompanied by venous congestion; and the other whose leaden-hued pallor and running thready pulse bear witness to an even graver condition of oxygen shortage and collapse or "shock." Venesection was valuable in the first type; it was dangerous in the second. Oxygen administration did good in both types; it was imperative in the state of pallor and collapse. But if the outstanding pathological changes are obvious, and two main lines of treatment—oxygen to combat asphyxia and venesection in suitable cases to relieve venous congestion—are firmly founded on experience, there is much that is still obscure. To what precise factors is the oedema attributable? That the alveolar walls and capillary endothelium must be injured seems certain, but

this damage is not irreparable. Many cases of grave pulmonary oedema did, in fact, recover completely without sequelae in the last war, though bronchopneumonia might sometimes ensue. Death in the acute stage usually occurs within the first thirty-six hours; when once this critical period is past the exudation seems to be steadily reabsorbed from the lungs. The lungs are engorged with blood during the development of the oedema, and it is probable that, apart from cellular damage, the dilatation of the capillaries is itself a contributory factor in increasing the permeability of the capillary walls, while cardiac failure, should it ensue, will make matters worse. Nothing seems to be known about the lymphatic drainage in these cases of acute pulmonary oedema; there may be some interference with this, and possibly the shallow rapid respiration which usually results from irritation of the vagal nerve endings in the lungs by these gases may not favour lymph flow so much as the more extensive movements of the chest in normal breathing. Attempts to diminish the permeability of the lung capillaries by calcium chloride proved useless in the last war, and it is doubtful whether modern calcium therapy will give any better result.

Heart muscle is very sensitive to oxygen deficiency, and cardiac failure is to be anticipated from this cause in severe cases of pulmonary oedema. But there is another factor that must be taken into account—the haemoconcentration which accompanies the exudation of fluid into the lungs and is most evident in the worst type of pallid cyanosis. The analogy with other conditions of "shock" is clear. How far increased viscosity of the blood due to this haemoconcentration, coupled perhaps with increased resistance in the damaged lung capillaries, imposes a greater strain on the right heart remains uncertain. In view of the possible accentuation of the oedema an attempt to reduce the haemoconcentration by transfusion of plasma cannot be justified without clearer experimental evidence than is at present available; although during the last war animal experiments in America were thought to show that intravenous infusion of saline after venesection had some beneficial effect. Cardiac stimulants have had their advocates, particularly on the Continent, but their substitution for oxygen therapy, which does so much to remove one of the principal causes of cardiac failure, is akin to flogging a tired horse; in association with oxygen they should have a better chance of success.

Although inhalation of the lung-irritant gases causes immediate coughing and choking and even retching and vomiting—symptoms more marked and persistent with some gases than others—these immediate signs of irritation often subside, and an interval, perhaps of several hours, may elapse before there is serious evidence of pulmonary oedema, which may then increase with alarming rapidity, often as the result of some muscular exertion. This delay, which introduces such difficulty in correctly appraising the real severity of the case in the early stages, may be attributable merely to the insidious development of oedema and anoxaemia, but the sudden accentuation of the oedema as a result of the circulatory changes and rise of blood pressure caused by muscular effort, the failure of a heart already weak-

ened by shortage of oxygen to meet the sudden strain of exertion, or possibly the liberation of such a substance as histamine from the damaged lung tissues, may all play a part. One thing is certain—that muscular exertion, which in any case means that the body uses up more oxygen, must be prohibited.

In its effect on the lungs that remarkable vesicant mustard gas differs greatly from the acute lung-irritant gases.* Whereas it is pulmonary oedema which endangers life in the case of the latter, this is not a serious feature with mustard gas unless the concentration of gas is very high; it is the damage to the respiratory passages that matters. Depending on the dose of vapour inhaled this may vary from the mildest laryngitis, with hoarseness and trivial cough, to the most intense destructive inflammation and necrosis of mucous membrane from the larynx to the smallest bronchioles, while bacterial infection of the necrotic debris may initiate a widespread septic bronchopneumonia. The full damage to the mucous membrane may take many hours to develop. In the last war there were rare cases of death from obstruction of the respiratory passages by debris and false membrane, but apart from these death was as a rule delayed and invariably due to bronchopneumonia. There is no specific remedy; treatment must follow the same general lines as in bronchopneumonia from other causes. Lewisite does not differ greatly from mustard gas in its action on the lungs, but is perhaps more prone to cause pulmonary oedema as well as grave damage to the air passages.

With acute lung-irritant gases there is a critical early period, and the aim must be to tide the patient over this. If this can be accomplished there is a good chance of ultimate recovery. With the vesicants there is no such critical early period; recovery is a question of the ability to withstand secondary infection.

RADIOLOGY TO THE HELP OF OBSTETRICS

Some forty-five years have elapsed since x rays were harnessed to medical science. Although their use is now extending to obstetrics, the new tool has hitherto been tardily accepted in this special field. There are reasons for this. The mechanical factors influencing labour are many and varied, and not the least important of them is the function of the uterine muscle, a matter concerning which x rays can give no help. Even with regard to the shape and size of the pelvis matters are far from easy, for the radiographic film tends to give a false impression of precision, and no easy method exists by which a three-dimensional problem can be solved by reference to one, two, or even three sets of pictures, in each of which the possibility of shadow distortion is ever present. Another difficulty has been the frequent lack of co-operation between radiologist and obstetrician. To quote from one recent paper: "The radiologist seldom has a clear understanding of the obstetrician's problems and needs: the obstetrician rarely appreciates the radiologist's difficulties and limitations." Nevertheless, substantial progress has of late been made in this difficult field, and contributions to the literature now follow each other in quick succession.

Clark Nicholson¹ of Moreton-in-Marsh has devised a highly accurate method of pelvimetry, and has painstakingly analysed his results according to modern statistical methods. He has estimated the frequency of variations of pelvic size, at both the brim and the outlet, and has correlated the difficulties in subsequent labours with the incidence of these abnormalities. Hastings Ince and the late Matthew Young² made a somewhat similar investigation among the obstetric patients of University College Hospital. From these valuable papers the following conclusions of general interest emerge.

The measurement of the true conjugate is greater than that stated in the standard textbooks: it is usually in the region of 4½ inches. There is little correlation between different sets of pelvic variations—for example, the shape of the outlet has no constant relation to the shape of the brim. External measurements are unreliable guides to the measurement of the true pelvis; this is especially so with regard to the external conjugate. Ince and Young state, however, that there is a fairly high correlation between the intercrystal measurement and the transverse diameter of the brim. According to the same workers there is little evidence of any relation between the pelvic characters, including the shape of the brim, and physical characters expressive of type of body build. This matter has also been recently thoroughly investigated by Greulich, Thoms, and Twaddle,³ who hold a somewhat different view, but agree that the correlation is too uncertain to be of value in predicting pelvic type. Nor is there any relation between pelvic characters and hirsutes and "masculine" distribution of pubic hair.

Three factors have a special influence on the incidence of delivery by forceps: these are the size of the pelvic outlet, the size of the subpubic angle, and the size of the baby. Nicholson, stressing the importance of the subpubic angle, writes: "We can now definitely state our conclusion that the great majority of the minor difficulties of labour, so far as these are due to contraction of the pelvis, are due to a contraction of the outlet, which is quite unassociated with any contraction or any alteration of the shape of the brim." Ince and Young prefer the old classification of pelvic contraction into the two main types of the flat and the generally contracted to the ten or twelve types suggested by Caldwell and Moloy, a classification which relies too much on subjective impressions regarding the shape of the pelvic brim. More recently Chassar Moir,⁴ working in the new Nuffield Obstetric Department at Oxford, has described methods, both clinical and radiological, by which pelvic contraction may be detected and the probable course of labour foretold. Like other workers, Moir stresses the importance of outlet contraction as the cause of difficult delivery, and prefers to call such pelves by the name of "funnel pelvis," as recommended many years ago by Whitridge Williams. While radiography gives the clearest indication of outlet contraction, much may be done by digital palpation: the distance between the tip of the sacrum and the under-margin of the pubic bone may be estimated, and so also the size of the subpubic angle and the distance between

¹ *J. Obstet. Gynaec. Brit. Emp.*, 1933, 45, 950.

² *Ibid.*, 1940, 47, 130.

³ *J. Amer. med. Ass.*, 1939, 112, 455.

⁴ *Edinb. med. J.*, 1941, 43, 361.

the spines of the ischium. Such methods do not aim at high accuracy, and in case of doubt recourse should be had to radiological examination. Moir stresses the value of the lateral view of the pelvis, obtained according to Thoms's technique, both before and during labour. This he considers the most valuable of any single x-ray examination; incidentally it is also the easiest picture to obtain. Pelvimetry without cephalometry is almost meaningless. A useful estimation of the size of the foetal head can usually be made from the lateral radiograph of the pelvis. In cases of difficulty additional help can be obtained from a film exposed for brim pelvimetry. In breech presentation the clinical test for disproportion between head and pelvis is impossible, and Moir urges that in such patients x-ray pelvimetry and cephalometry should always be employed. Many of the difficulties and dangers encountered in breech delivery, particularly in primigravid women, could thus be avoided. In our present issue (p. 543) O'Sullivan and McLaren, in a paper on radiology in disproportion, again stress the value of the lateral or profile view of the pelvis. By its use not only may the obstetric conjugate be measured but the curve of the sacrum may be demonstrated and the antero-posterior dimension of the cavity and outlet easily determined. A simple method is suggested of estimating the "fit" of the head and pelvis. This test will be of most value when the foetal head is conveniently positioned to show its shortest diameter; when, however, it is otherwise positioned a "negative" finding would have to be accepted with reserve.

Enough has been said to show that radiology is fast becoming an accepted tool in obstetric practice. But all new tools must be used with caution. And here we may once more quote Nicholson: "As is the case with most new methods, radiological pelvimetry has suffered more in reputation from the enthusiasm of its followers than from the criticism of its detractors. Nobody is so foolish as to claim that the radiologist is to supersede the obstetrician in the judgment as to when a Caesarean operation is necessary; but nobody should be so foolish as to claim that the obstetrician can afford to neglect precise information about the bony pelvis with which he has to deal."

GOVERNMENT HOSPITAL POLICY

Last week the Minister of Health made a statement in the House of Commons on the Government's post-war policy on hospitals which is of the highest significance to both voluntary and municipal hospital authorities. This policy is based on the solid foundation of making available by means of a comprehensive hospital service appropriate treatment to every person needing it. The duty is to be laid on major local authorities, acting in co-operation with the various voluntary agencies concerned, to secure the provision of this service "by placing on a more regular footing the partnership between the local authorities and the voluntary hospitals on which the present hospital services depend." The service will be based on larger

areas than those of existing local authorities: this is an endorsement of the policy of regionalization with which everyone is now so familiar and to which modern conditions and logic obviously point the way. The Minister has already had preliminary discussions with representatives of the voluntary and the municipal hospitals, and is instituting a survey of the hospitals in London. In his statement he referred to the valuable preliminary work that had already been done in the Provinces under the auspices of the Nuffield Provincial Hospitals Trust. In order to avoid waste and overlapping the Government's policy is to secure the provision of the more specialized services at teaching hospitals and at other centres which serve the larger regions contemplated.

So far as the important question of the payment for this reorganized service is concerned, the Government recognizes the principle that patients should make "a reasonable payment" towards the cost, whether through contributory schemes or otherwise; the limiting factor, it may be assumed, being the patient's capacity to pay. The provision of a reorganized hospital service will put a heavy burden on both voluntary and council hospitals, and the Government has established the highly important principle of making Exchequer moneys available for the increased cost that will be incurred. This decision is significant in view, especially, of the State help which will be needed for rebuilding damaged hospitals after the war. It may be remembered that after the last war, when there was a steep fall in the incomes of the voluntary hospitals, the Government compensated them direct to the extent of half a million pounds. As the duty of securing the reorganized hospital service is laid upon the major local authorities, Exchequer grants will be made to them for any new burden that is incurred in providing and maintaining their own hospitals and in contributing to the expenditure of voluntary hospitals.

Those who have fears for the future of the voluntary hospitals may wonder whether this financial channel will give the local authority increasing control over them; whether, in fact, this is a step towards converting the voluntary into council hospitals. So far as the teaching hospitals are concerned, some reassurance comes from the statement that they will be assisted by way of increased educational grants, presumably through the University Grants Committee; but should the financial assistance to the voluntary hospitals through council channels become large, then, it might be feared, so would the control of the destinies of these hospitals. While the various agencies which provide the hospital service of the country will jealously watch their rights, they will, it is certain, be eager to meet the obligation that is now to be put upon them. The Minister's statement brings to solid earth what has long been in the air, and asserts as Government policy the three important principles of regionalization, co-operation between voluntary and local authority bodies, and, last but not least, State aid to the hospitals of the country.

AN INTERNATIONAL STANDARD FOR VITAMIN E

We are asked to announce that an international standard for vitamin E has been established, and that, as in the case of the international standards for the vitamins A, B, C, and D, the National Institute for Medical Research, Hampstead, acting on behalf of the Health Organization of the League of Nations, has undertaken its supply to laboratories, institutes, and research workers throughout the world.

Synthetic racemic α -tocopheryl acetate ($C_{55}H_{102}O_6$) has been adopted as the international standard for vitamin E. The investigation of the chemical, physical, and biological properties of this substance, its suitability for adoption as the international standard, and the manner of its application in biological assay was carried out, at the request of the Health Organization of the League of Nations, by the Vitamin E Subcommittee of the Accessory Food Factors Committee of the Lister Institute and the Medical Research Council. The subcommittee was able to enlist the co-operation of experts in fourteen laboratories in Europe and America, and as a result it was able to recommend the adoption of synthetic racemic α -tocopheryl acetate as the international standard for vitamin E. The subcommittee further recommended that the international unit for vitamin E should be defined as the specific activity of 1 milligramme of the standard preparation, this quantity being the average amount which, when administered orally, prevents resorption-gestation in rats deprived of vitamin E.

In normal circumstances the results of the co-operative investigation would have been submitted for discussion at the third International Conference on Vitamin Standardization, which had been arranged for the autumn of 1939. On account of the war this conference could not be held. The report and recommendations of the subcommittee have, however, been placed before those members and officers of the League of Nations Permanent Commission on Biological Standardization and of the International Conference on Vitamin Standardization who were available and accessible, and these consented to accept the responsibility of taking such decisions as would normally be accepted by a properly constituted International Conference and by the Permanent Commission. They have accordingly adopted the proposed standard for vitamin E, accepted the recommendation defining the international unit, and authorized the National Institute for Medical Research, Hampstead, to proceed with the distribution of the standard.

The international standard for vitamin E is issued in the form of a solution in olive oil of which one international unit is contained in 0.1 gramme. It will be supplied to directors of national control centres in those countries in which these have been established, for local distribution; also to laboratories, institutes, and research workers in this country, and in those countries in which national control centres have not yet been established. Application should be made to the Department of Biological Standards, the National Institute for Medical Research, Hampstead, London, N.W.3.

A MEDICAL OFFICER'S CONSCIENCE

Dr. W. A. McLennan, medical officer of health for the borough of Dudley, has been suspended from his post for the duration of the war by the borough council for the sole reason that Dr. McLennan has registered his conscientious objection to serving with the armed Forces. We print in the *Supplement* the correspondence between the B.M.A. and the Ministry of Health and the Town Clerk

of Dudley. The Association has first of all protested against this action on the part of the borough council, and, secondly, has refused to accept for advertisement in its columns a notice inviting applicants to apply for the vacant post—two actions which will no doubt be endorsed by the medical profession generally. We are not concerned here to discuss the ethical basis of Dr. McLennan's conscientious objection, but we may feel sure that he looked deeply into his conscience before making what is in these days a difficult decision. It was laid down by Mr. Chamberlain at the beginning of this war that there was to be no persecution of those whose scruples forbade them to take a course which their conscience and religious principles did not allow them to follow. There is no reason to believe that since Mr. Chamberlain's statement in the House of Commons there has been any change in Government policy, and the Dudley Borough Council's decision is particularly lamentable in the case at issue, because of the need for civilian doctors. As the correspondence points out, Dr. McLennan is a key officer of recognized experience and efficiency, and the number of suitable men available to fill his post is very small. This kind of local arbitrary action against declared Government policy and against the civilized principle of a man's right to adhere to deeply grounded convictions is difficult to tolerate.

STREPTOCOCCAL ULCERATION AROUND WOUNDS

The writings of Meleney, to which reference has several times been made in these columns, have defined and now made generally familiar a form of spreading ulceration of the skin which sometimes develops around infected operation wounds, usually of the chest or abdomen. Zinc peroxide is said to be a specific for this condition—and has indeed been found useful as an application to various other types of indolent septic area, especially where anaerobic infections exist—though there are puzzling features about impurities in the zinc peroxide used and the inactivity of some preparations which led us to suggest that perhaps oxygen liberation is not the *modus operandi* of this treatment, as its author and others have supposed. According to Meleney the cause of the spreading skin ulceration described by him is a micro-aerophilic haemolytic streptococcus, but the characters of this organism have not, so far as we are aware, been as fully investigated as they deserve. That a streptococcus is responsible, and that it tends to be micro-aerophilic in its habit of growth, every bacteriologist knows who has met this interesting condition. Whether in all its characters other than atmospheric requirements it is simply a *Streptococcus pyogenes* is another matter. It is not even known whether these characters are constant, and the observations of J. Reicher¹ suggest that they are not, since he has had a small series of cases with features which, according to Meleney's definition, are anomalous. Of two typical cases of undermining and spreading ulceration one was found to be due to a streptococcus of the type described by Meleney, whereas in the other the organism was non-haemolytic. On the other hand, both these types of streptococci, haemolytic and non-haemolytic, though micro-aerophilic in each case, were found in lesions in other patients which had different characters, showed no spreading tendency, and responded to other forms of treatment. This short series of cases suggests the need for further study of such streptococci. If a number of strains could be collected from typical cases of spreading ulceration as described by Meleney, they

¹ *Surg. Gynec. Obstet.*, 1941, 72, 651.

should be investigated by the various methods employed for classifying streptococci, of which there are many. If they are in fact to be classed as *S. pyogenes* it would be interesting to know whether they belong to any of the known Lancefield groups. The fact that similar micro-aerophilic streptococci can be found in lesions with other characters is of course no evidence against the specific nature of the lesion described by Meleney, but it does raise the questions of the distribution and source of these organisms. Streptococci similar in their atmospheric requirements and in their morphology—characteristic points being the small size of the individual coccus and the great length of its chain—are not uncommon in lung and cerebral abscesses. Are they obligatory pathogens derived from an external source, or do they—as appears more likely—sometimes exist as saprophytes in the mouth or lower bowel? As opportunities occur, these are matters which should repay investigation.

DIGITALIS PREPARATIONS COMPARED

There are few official but many proprietary preparations of digitalis; new forms of the latter appear from time to time, often with claims of superior therapeutic properties combined with freedom from toxic effects. It has generally been found, however, that these attributes, therapeutic and toxic, are inseparable and vary simply with the activity and dose of the preparation. A comparison of six commonly used forms of the drug has been made by W. Evans,¹ based on the results in eighteen patients with heart failure. All had rheumatic heart disease with mitral stenosis and auricular fibrillation, which is particularly suitable for the investigation of digitalis action. Each preparation was given for fourteen days in the doses reckoned equivalent on the basis of biological assay, and at the end of each fourteen-day period the heart rate and the severity of symptoms and signs were estimated. Improvement in the latter coincided closely with reduction in heart rate, although the optimum rate varied considerably from patient to patient, being as low as 52 per minute in one and as high as 115 in another. The satisfactory control of symptoms combined with absence of toxic effects and decrease in heart rate was obtained with all six preparations, which in the order of efficiency of the doses used were: powdered digitalis leaf; digitaline (Nativelle); digifoline (Ciba); digoxin (Burroughs Wellcome); tincture of digitalis; and digitaline (Allen and Hanburys). A trial was also made of three other drugs which have a digitalis-like action and which have been vaunted on the Continent and in America as being equal or superior to digitalis itself. These three drugs—folinerin obtained from the oleander tree, strophanthin, and ouabaine (a strophanthin glucoside)—proved unsatisfactory. Strophanthin and ouabaine did not lead to any improvement but often caused toxic effects, while folinerin was followed by improvement in only two of the eighteen patients. Finally coramine (nikethamide) and cardiazol (leptazol)—two drugs sometimes described as heart stimulants—were given. They were without avail in the control of symptoms, and because of this had to be replaced by digitalis after seven days. Moreover, they appeared to cause toxic symptoms. Evans's study indicates that the dried leaf is a very satisfactory preparation of digitalis. It is favoured by many cardiologists to-day just as it was by Withering over 150 years ago; in fact we have little better remedy than the "Flower of Physicians," except that there is now at our disposal a pure glucoside of digitalis, which may be used intravenously when a quick on is needed. The leaf, moreover, is cheap, the

cheapest with the exception of the tincture. In this study the effects of different preparations were compared on the same patient—the only possible way, as each patient is a law to himself. If this be accepted, it follows that potency in man cannot be based alone upon biological assay, nor can the correct dosage be based upon body weight or any other preliminary consideration, but simply upon the clinical results as shown by continued observation. After 150 years we still need to draw the moral from Withering's statement: "The more we multiply the form of any medicine the longer we shall be in ascertaining the real dose."

WELFARE OF BRITISH BLIND

The seventy-third annual report of the National Institute for the Blind (224, Great Portland Street, W.1) is a record of fine achievement in conditions that have entailed the loss of valuable lives and the wrecking of a sunshine home for blind babies, of the Institute's talking-book recording studio, of the headquarters of its home industries department, and other premises. Yet, though the calm of its normal procedure had been disturbed and progress along familiar lines partially diverted, the report declares that the problems, the difficulties, and even the dangers of the times have "enlivened the work, tested its vitality, revealed its ingenuity, and proved its capabilities under abnormal stresses." Blind readers have continued to receive their embossed newspapers, students to have their textbooks transcribed into Braille, men and women to be trained as masseurs; and similar continuity has existed in each of the Institute's other services to the sightless. Time has even been found to send out books in Moon type to the aged blind of America and the Empire. Many special wartime duties have been undertaken in respect both of people blinded by enemy action and of the new needs of those already blind. It can to-day offer immediate help to every war-blinded civilian as the casualty occurs, and homes of recovery for this purpose are now operating in various parts of the country. The gift of one of these homes by the American public was a timely and significant act.

Dr. R. D. Gillespie, who now holds the rank of Wing Commander in the Royal Air Force, has been granted leave of absence by the Air Ministry to report to the American medical profession his first-hand observations on the psychological effects of air warfare on the British public. He is visiting America at the request of the Salmon Committee on Psychiatry and Mental Hygiene of the New York Academy of Medicine. He will deliver the Salmon Memorial Lectures in the New York Academy Building on November 17, 18, and 19, speaking on "Psychoneuroses from the Standpoint of War Experience." The New York lectures will be followed by addresses before the Chicago Neurological Society, the Chicago Institute of Medicine, and the Illinois Psychiatric Society in Chicago, and lectures in Toronto, Ontario, and San Francisco, California.

Mr. W. C. W. Nixon, F.R.C.S., F.R.C.O.G., will deliver the fourth William Blair-Bell Memorial Lecture, on "Diet in Pregnancy," before the Royal College of Obstetricians and Gynaecologists, 58, Queen Anne Street, W., on Saturday, October 25, at 2.30 p.m. Medical practitioners not members of the College will be welcomed.

¹ Brit. Heart J., 1940, 2, 51.

THE ARMY MEDICAL OFFICER

BY

J. T. ROBINSON, M.A., M.D., B.Ch., D.T.M.&H.

Major, Royal Army Medical Corps

As the war proceeds and the field of operations extends, more officers and men are required to fill the fighting Forces. To keep pace with the extension of these commitments in fighting personnel the age groups for recruitment are being gradually raised. The medical needs of the armed Forces must be met and doctors will be concerning themselves with the implications of their calling up. Family disruptions, temporary severance from practice and civil appointments, and financial adjustments form some of the considerations which will face these practitioners, who will also be concerned with their future in one of the fighting Services.

The medical profession is privileged to a degree which few other professions enjoy in war. Medical students who have completed two satisfactory terms in anatomy and physiology are reserved to enable them to graduate, doctors are not required to serve in the ranks but are granted commissions on being called up for service with the armed Forces of the Crown, while the medical officer is employed in work which is essentially in touch with, and part of, his professional work.

Many doctors liable for service will be recruited into the R.A.M.C. and will be anxious to have some information regarding what is expected from them as medical officers, and of the steps taken to adjust them to their new work and environment. This is the purpose of this brief article. It is not intended to describe in detail the duties which a medical officer in charge of effective troops is expected to perform. These are fully depicted in the Regulations of the Army Medical Services, and in a recent pamphlet, *Notes for Medical Officers, 1941*, which is issued to every serving medical officer. Colonel Midcletton¹ has ably described the work of the regimental medical officer in his interesting Honyman Gillespie Lecture delivered in September, 1940, while Captain Pozner² has recently given his personal experience and impressions of regimental medical practice. Medical practitioners not in the Services will therefore have some idea of the responsibilities of the medical officer in the Army.

The Corps and its Function

The Royal Army Medical Corps first came into being on June 23, 1898, by a Royal Warrant of Queen Victoria, and the badge with the motto "In arduis fidelis" was granted. In the same year the Corps made its first appearance with an Army in the field in the Nile Expeditionary Force. With the Corps organization, military titles, and a secure position in the military hierarchy came a great impetus to medical and surgical keenness. Officers had to select a special subject, and research was marked out as one of the high roads of advancement. Men like Bruce, Leishman, and many others adorned the Corps.

From its inception the Corps has played a noble part in every campaign in the scientific efforts to discover and check disease and in the efficient care and treatment of the sick and wounded of the Armies in the field. From the war of 1914-18 it emerged with outstanding credit, and the names of officers and men were prominent in the lists of awards for valour. When the history of the present struggle is written the Corps will assuredly be given an honourable place and will be depicted as having lived up to the great tradition of the past. The doctor of yesterday who has become the medical officer of to-day will no doubt adorn once again the lists of those awarded for bravery and bring glory to the medical profession and the Corps.

To the mind of the uninitiated the function of the Corps presents a series of pictures in which the wounded soldier is seen receiving first aid on the battlefield, moving to rear by field ambulance, being cared for in well-equipped hospitals by efficient doctors and nurses, and finally leaving hospital restored to duty. These concepts are correct but fail to give the whole picture. To them must be added the responsibilities of (a) the prevention of disease by necessary sanitation measures; (b) the collection, evacuation, and treatment of the sick and wounded in all theatres

of war; (c) the provision and distribution of medical equipment and supplies; (d) the maintenance of morale by a medical organization which imbues officers and men with a conscious confidence that immediate medical aid is available at all times; (e) the preparation and preservation of records of sick and injured for the adjudication of claims for disability with justice both to the Government and to the soldier, and also for statistical purposes; and (f) the training of personnel to carry out these responsibilities.

In all these the medical officer has an important part. His duty is the conservation of man-power and the maintenance of a high standard of physical fitness and morale throughout the Army. Famous military commanders have frequently spoken in high praise of the conscientious and efficient medical officer. General Thorne,³ commander of an Army Corps, in an address to medical officers, has stressed that the first and most important contribution that a medical officer can make to fighting efficiency in the Army is by his efforts to improve the standard of "man-mastership." He pointed out that economy of force was vitally important in war, and that the medical officer by his professional efficiency does much to avoid unnecessary wastage of man-power when a soldier either mentally or physically sick was returned to his unit a fit man. He emphasized that the most striking lesson he had learned as a Divisional Commander was the reliance placed by a commanding officer on his medical officer to raise the standard of human relationships in the unit to a high level. Concluding his address he expressed the view that the management of men was an art, but that the medical officers, by using their technical knowledge, could make it almost a science.

Civilian Medical Practitioner to Medical Officer

Readers are aware of the machinery of the Central and Local Medical War Committees for the supply of medical officers to meet the demands of the Services, of the arrangements made to protect the practices of those who join, and of the responsibilities of these committees in safeguarding the medical needs of the civil population to meet all emergencies. It may be of interest to them to learn something of what transpires when doctors are recruited for commissions in the Royal Army Medical Corps.

The War Office on receipt of these nominations makes arrangements for the interview and physical examination of each candidate. At the interview the latter is requested to fill in a special form regarding details of qualifications and other relevant matter relating to appointments held, for the information of the Medical Department. The candidate is officially informed of his acceptance or otherwise for a commission. All commissions are in the rank of lieutenant, and those who have had service in the R.A.M.C. in the last war in the rank of captain are eligible for promotion to this acting rank from the date of commission.

A careful record is kept in the Medical Department of the War Office of the qualifications and experience of every candidate, so that each may be placed at some future date in an appointment for which his talents are considered best suited. All documents of those possessing higher qualifications and experience are submitted to the consultants in the branch of medicine or surgery in which an officer has shown special aptitude and skill. If considered to possess the necessary experience and qualifications for employment in his selected subject efforts are made to appoint him to a post within establishment where he can continue such work. If none is immediately available a careful record is kept for future employment when a vacancy occurs.

Training Courses

In the less venturesome there is an element of anxiety which inhibits the desire to take on a new life and dwell in a new environment, leaving behind something sure for an indefinite future. Individuals in the medical profession particularly take pride in carrying out work in which they are masters. They are reluctant to take up employment which means new and additional responsibilities for which they feel unprepared. This is perhaps the view presented to the minds of those who suddenly find themselves for the first time in the uniform of a medical officer of the R.A.M.C. Such anxiety is unnecessary, because just as the newly joined gunnery officer must learn the technical and intricate details of weapons which he has

never before understood, so special arrangements are available to acquaint and train the newly joined medical officer in the principles and elementary knowledge of his more military duties so that he will be happy and well equipped for his future environment and responsibilities.

Those granted emergency commissions are expected to report to one of the R.A.M.C. Depot and Training Establishments for Medical Officers. Here he is initiated into the organization and administration of the Corps, the general organization of the Army, and co-operation with other arms and Services. He receives instruction in field medical work, map reading, the use of the compass, P.A.D. (the Army's A.R.P.), and other items of essential value in the battlefield. He is also given lectures and demonstrations of the records and reports which he is expected to maintain, and how and when these should be rendered. He is given a free issue of books and pamphlets on all relevant matters which he is expected to know. These are carried with him and are available for guidance and ready reference. This course now lasts for three weeks, after which one week is spent at the Army School of Hygiene, where the professional activities of the medical officer are primarily directed to environmental sanitation, water supply, sewage disposal, anti-malarial work, and inspection of rations. On completion of this four-weeks course the officer is posted for duty to either a field medical unit, hospital, training centre, or regiment according to the requirements in medical personnel. Wherever he is sent he will still have much to learn, but will never be completely divorced from his professional work if interested and conscientious. As the exigencies of the Service demand, medical officers are moved from one appointment to another, and may be sent to all parts of the world where troops are required. For those proceeding to tropical climates courses are arranged in tropical medicine and hygiene. These are held at the London School of Hygiene and Tropical Medicine and the Liverpool School of Tropical Medicine by the kindness of the respective deans, while other courses are held at the Royal Army Medical College, Millbank, London. Courses are also given in the medical aspects of chemical warfare to all officers. All who have attended testify to the valuable and practical knowledge which they assimilate from these courses.

The Medical Officer and the Unit

The medical officer in charge of effective troops is in the unique position of being able to study the newly joined recruit, especially his reaction to military training and environment, treating him when he is sick or injured, and finally deciding on his ultimate disposal. In the university and medical school the teacher is never tired of impressing on the medical student to "observe." The qualified doctor therefore should possess this essential attribute to a high degree, and it is this that makes the life of the medical officer interesting and provides him with a technique which, if properly employed, will enhance his knowledge of humanity and better equip him for his return to practice after the war.

The first thing which strikes a medical officer in dealing with soldiers is that they differ considerably from the patient in civil life. There are few scrimshankers in the Army of to-day, but these few prey on the kindness and inexperience of the newly joined medical officer, and if allowed to get away with their frivolous complaints can quickly demoralize a whole unit. Others will carry on with disabilities and ailments until they drop. The action and behaviour of individual soldiers to injury and disease present features of unique study under the rigours and monotony of Service life.

The medical officer has also a definite duty to his country to equip himself with a practical knowledge of psychiatry in order to differentiate between functional and organic disease. The frequent attendance of a soldier at sick parade will give him opportunities to observe the temperament, character, and intellectual qualities of the individual, and lead to a full investigation of his physical and mental capacity. Co-operation with the psychiatric specialist will add to his own knowledge, in many cases lead to the cure of the soldier, in others to the soldier's adaptation to more suitable employment within the Army, while those unsuited for Army life will be quickly sifted out, thereby avoiding unnecessary expense and wasted time in training. A

thorough physical examination of every man who reports sick is the first duty of every medical officer.

In order to take his proper place as the adviser to the commanding officer of the unit in all matters relevant to the prevention of disease and the preservation of the health of the men in a unit the medical officer must have a thorough knowledge of the propagation, prevention, and treatment of infectious diseases, sanitation, water and its purification. On him rests the decision as to whether the Army ration is fit or unfit for human consumption.

The efficient medical officer will also identify himself with the interests and daily routine of the officers and men of the unit of which he has medical charge. He will interest himself in their training, take pride in reading and understanding the various Army manuals connected with the weapons they use and the vehicles they drive. He will march and play with them, enter into their social activities, and be with them in their hours of trial to cheer and encourage the faint-hearted, and succour and give aid to the wounded. By so doing he will not only gain the respect and affection of the unit, but will increase in wisdom and knowledge by his personal contact and co-operation with all types and conditions of men. His wide interests should stimulate his professional acumen, and will enable him to take his true place as doctor, guide, philosopher, and friend to all.

Conclusion

The great men of the profession have always taken pride in acquiring knowledge on subjects outside their medical attainments, and many have added honour to the profession in politics, law, and other spheres. To them every subject and person is of interest and a new experience gained. The medical officer has the opportunity to take his place with the "Great" in this respect.

To combine medicine with efficient modern soldiering has the immediate aim of winning the war. Many other results follow also when a doctor takes this line whole-heartedly, and the benefits to the soldier, Army, community, and nation are obvious to all. Only in this way can the medical officer give the maximum service to his country, and no sphere offers such opportunities for dealing with the individual problem of men. No other line of work offers the same chance of affecting the social future and well-being of the country as that of the whole-hearted intelligent medical officer.

In view of the many apparent duties and interests which will absorb his time the prospective medical officer will be concerned with keeping himself abreast of modern developments in medicine and surgery. The War Office has ensured that modern research and therapeutics consistent with the latest practice of medicine and surgery are available for each medical officer in a concise form. Each month the *Army Medical Directorate Bulletin* is issued free to all, and the *Bulletin of War Medicine* produced by the Medical Research Council is also available. The latter contains abstracts of relevant articles in all branches of medicine, surgery, and kindred subjects, and is a mine of information.

I wish to thank the Director-General, Army Medical Services, for permission to publish this article.

A tribute to the good will and sympathy of Americans in helping to relieve the distress of war in this country has been paid by the Lord Mayor of London in accepting on behalf of the London Chest Hospital, Victoria Park, E., a parcel of valuable drugs presented by Mrs. Edward Murrow of the Bundles for Britain Movement, which has adopted the hospital. The drugs, which had been flown to this country, were contributed by nurses in Dayton, Ohio. The Lord Mayor and Lady Mayoress were paying a visit to the hospital to inspect the progress made since it was severely bombed in the spring, and he congratulated the staff on the splendid job they had done. All the departments were open, including wards for in-patients.

THE MEDICAL DEFENCE UNION

The annual general meeting of the Medical Defence Union took place on September 30. The report of the council testified to continuing success and prosperity, as evidenced by 1,368 new members elected during the year, a net gain of 688, bringing the total membership up to just over 24,000. It was stated that the war had not brought to medical practitioners any immunity from litigation based on allegations of negligence or malpraxis. Several serving members had been seriously perturbed by the litigious activities of aggrieved patients or their relatives. New problems had emerged from the conflict of partnership and legal obligations with national and local demands for the services of medical practitioners. Partnership deeds had required special amendments and in some cases temporary determination. Arbitration had been resorted to in rare cases when a partner refused to waive, cancel, or amend his legal rights in the partnership deed or to release a junior who desired or was required to join the Forces. Practitioners heavily committed financially by the purchase of their practices and practising in bombed or evacuation areas had been interviewed and advised on their special difficulties. The amount expended by the Union last year on indemnity claims and insurance was £6,117, and on law charges £4,587. Six cases were cited in which the aggregate amount expended in costs and damages was close upon £4,000, and the total received in yearly subscriptions from the six practitioners concerned since they took up membership was only £60. After a long discussion the council had decided to admit to membership practitioners of non-British nationality, provided they satisfy certain criteria and also undertake on the cessation of hostilities to give notice of their intention to withdraw from membership. Mr. St. J. D. Buxton had been elected president of the Union in succession to the late Mr. Eric Pearce Gould, and during Mr. Buxton's absence on military duties Dr. de Bec Turtle had served as acting president. The financial statement for the year 1940 was presented by the treasurer, Mr. E. D. D. Davis, who expressed the view that the report was self-explanatory and did not call for comment on its details. The report was immediately approved and adopted unanimously. Mr. A. D. Griffith, Dr. A. Lyndon, and Dr. G. de Bec Turtle were elected members of the council, and at a subsequent meeting of the elected members of council Dr. Turtle was appointed president of the Union for the session 1941-2, and Messrs. Hempsons were re-elected the solicitors to the Union.

Local News

ENGLAND AND WALES

The Tavistock Clinic

The Tavistock Clinic (the Institute of Medical Psychology) celebrated its twenty-first birthday by a luncheon, over which Lord Alness presided, on September 29. The Marchioness of Reading, in proposing the toast of "The Clinic," sketched its progress from small things until just before the war, when ninety doctors, including clinical students and postgraduate assistants, were working in association with it. She said that the work was being continued in temporary quarters at Westfield College, Hampstead, and the home at Malet Place, Bloomsbury, had been destroyed by enemy action, but it would again have a habitation of its own, for its work would be more needed than ever after the war. Even though the British people did not get neurosis as a result of bombing, they were very likely to get it in the dread of starting life over again on a new basis. Lord Alness claimed that the clinic was an institution of national importance; he knew of no other which had stood up more gallantly to the shock of war. Lord Hollenden, the treasurer, mentioned the need for reducing the debt which weighed so heavily on the work. Colonel J. R. Rees, the medical superintendent, reminded the company that the clinic was started on the understanding that it should run for only three years, by which time it was believed that the hospitals would have developed a sufficient number of out-patient psychiatric clinics to meet the need. In fact, however, the Tavistock Clinic had never been able to catch up with the demand for its services, and indeed one of its problems had been an unshiftable waiting

list. Nearly 15,000 patients had passed through the clinic since its foundation, and before the war it was giving 26,000 medical treatments a year, not taking into account the social work and ancillary services. It was also the first child guidance clinic in the country, although it never took that name. He added that of the group of doctors working at the clinic before the war, some twenty were now specialists in the fighting Services, fifteen were in the Emergency Medical Service, and eighteen in the Ministry of Pensions and various other institutions, mostly out of London, leaving about twenty-three, mostly women doctors, carrying on a splendid part-time service at the clinic. More children had been seen during the first eight months of this year than during the corresponding period in any of the previous five years. He, too, believed that after the war there would be a vast increase in psychiatric problems. When once the tension was relaxed signs of strain would appear, and then the clinic would be able to render even fuller service.

Queen's Institute Nurses

The Queen's Institute of District Nursing reports that during 1940 maternity cases to the number of 85,242 (in which no doctor had been engaged for the confinement) were attended by 1,530 Queen's nurses and 2,782 village or other nurse-midwives. Rather more than one-fourth of the patients were primiparae. The maternal death rate was 1.74 per 1,000 live births, of which 0.03 was due to non-puerperal causes. The death rate was slightly higher in rural than in urban areas (1.78 and 1.39 respectively). Deaths among the primiparae were 31% of the total maternal deaths. Medical aid was summoned for the mother in 31,311 cases and for the infant in 5,692 cases. An analysis of 138 maternal deaths shows that 31 were due to sepsis, 50 to accidents of labour, 17 to eclampsia, 19 to embolism, and 21 to complications. Of the fatal cases 45 were not delivered by the midwife, as it was necessary to summon medical aid before the birth. The number of forceps deliveries was 4,572, or 5.4% of the total confinements. The need for more frequent ante-natal visits, particularly during the last two months of pregnancy, is emphasized. This is particularly evident from the report on deaths from eclampsia: in 10 out of these 17 cases no symptoms were noted before coming into labour. In addition to these cases in which no doctor was engaged for the confinement, the nurses or nurse-midwives acted as maternity nurses in 36,560 cases in which a doctor had been engaged. The maternal death rate among these was 2.79.

Prevention of Eye Injuries: Exhibition in Edinburgh

An exhibition of appliances for the protection of the eyes in industry has been opened in the Eye Department of the Royal Infirmary, Edinburgh. It has been arranged by the W. H. Ross Foundation (Scotland) for the Study of Prevention of Blindness. At the opening of the exhibition, which conveys its information to a great extent by means of a series of enlarged photographs, Dr. Arthur H. H. Sinclair said that it was hoped that it would help workers engaged in industry, particularly in dangerous work, to realize the importance of employing the protective measures which were available. Colonel R. M. Dickson, director of the Foundation, said that under the Factories Act about 8,000 eye accidents were reported each year. Analysis of 1,000 cases of eye injury in the ophthalmic department of the Glasgow Royal Infirmary showed over 70% to be occupational in origin, the great majority of these being among metal workers and coal miners. The hazards to sight had been greatly increased recently by the expansion and speed-up of production, with large numbers of men and women in new jobs, working long hours, often under poor lighting conditions the result of the black-out. The strict enforcement of rules concerning the use of goggles and other protective devices was proving the most effective means of reducing eye injuries.

W. L. Donohue (*J. Pediat.*, 1941, 19, 42) records a fatal case of mumps encephalitis in a girl aged 5 years, with a review of the literature. The fundamental lesion was a perivascular demyelination similar to that seen in other cases of post-infective encephalitis.

The recent radiographic survey among Army recruits in America by H. R. Edwards and D. Ehrlich (*J. Amer. med. Ass.*, July 5, 1941, p. 40), even though carried out by a comparatively expensive method, shows how a financial saving of considerable proportions can be effected by wise expenditure at the right time—in this case a saving on pensions. Tuberculosis among the civil population of Great Britain may not be a potential source of future financial outlay of this kind, but its steady increase will certainly make further demands on finance, for the public health and public assistance activities associated with the general burden of tuberculosis within the community. I suggest that the time has come when the authorities concerned should give serious consideration to the many implications arising from the steady increase in tuberculosis which is now apparent. The war effort must be the dominating factor in all national activity of the moment, but we might find it would be best served, so far as this problem is concerned, by taking action now rather than later.—I am, etc.,

The Spread of Poliomyelitis

SIR,—Your recent annotation (August 30, p. 311) has drawn attention to one of the most interesting unsolved epidemiological problems of the present day, and it is the object of this letter to point out one method whereby practitioners attending cases of the disease can materially aid in research.

It is generally believed that in the majority of cases the poliomyelitis virus spreads by means of infected droplets of nasopharyngeal secretion. It is thought that these droplets are inhaled and that the virus passes from the roof of the nasal cavity along the olfactory nerves to the olfactory bulbs, and thence backwards by nerve tracts to the thalamic region and on to the spinal cord. Actual observations on man in support of this theory are, however, scanty, and some workers affirm that this is not the commonest mode of spread.

Much of value would undoubtedly be learnt if post-mortem examinations were carried out on all fatal cases of poliomyelitis, and the olfactory bulbs and tracts carefully dissected out and submitted to expert histological examination for the presence of inflammatory changes. If a considerable number of such observations were recorded it would be easier to assess the likelihood or otherwise of the olfactory route being the usual channel of entry of the poliomyelitis virus into the body.

It may be said that at the moment the few observations recorded do not favour this portal of entry, as, in the majority of cases examined, changes in the olfactory bulbs and tracts have been scanty or absent.—I am, etc.,

Treatment of Scabies

SIR,—Since my letter in the *Journal* of January 25 (p. 135), in which I described my experience of treating scabies by sulphur given internally, there have been many letters, references, and articles on the subject of scabies and its treatment, but only three of them refer to sulphur taken internally.

I read with interest the practical and instructive article by Surgeon Lieut. J. F. Buchan on the comparison of treatments of scabies (August 16, p. 227), but I am sorry he did not include in his series cases treated by internal sulphur alone, and in those he treated by combined internal and external methods he does not mention one reaction to taking sulphur internally, which to me is the most important, and that is that all silver coins or ornaments on the patient turn black, due to H_2S exhaled from the skin. I believe, and I am also well informed, that it is the H_2S which kills the acarus, and it also disinfects the clothing and prevents recurrences. An adjustment of the dose controls any tendency to looseness of the bowels; my patients were mental cases, and one drachm of the confection just acted as an effective laxative.

In the scrub and ointment treatment you make abrasions, the exudation from which combines with the sulphur in the ointment and gives off H_2S to kill the acarus. Surgeon Lieut. Buchan truly says that this is a dirty method; it is not only dirty, it is expensive as regards laundry and deterioration of clothing and bed-linen, and unless there is a very plentiful supply of hot water, which means plenty of coal, it can be more than dirty; in addition it requires the complete co-operation of the patient. Dr. N. F. Cooper in his note (April 19, p. 616) confirms my experience.

I am indebted to Dr. A. M. H. Gray of University College Hospital for informing me that sulphur internally was used for scabies in the first half of the nineteenth century, and in his letter (February 8) he gives extracts on the subject from the books of doctors who had written about it, including Hebra, the Viennese dermatologist. Dr. Gray very logically says in his letter that "it is difficult to believe that a remedy—which was evidently at one time in constant use—would have been discarded if it had been as effective as Dr. Berncastle imagines." I submit an explanation why internal sulphur was dropped which I think is reasonable.

I deduce from two facts. First, in the reign of King George III there was a heavy tax on soap (glycerin was not needed for explosives in those days); the tax was as much as the cost of the soap, and was not repealed until 1853. Secondly, bathrooms and hot-water systems did not exist in the average Georgian and early Victorian houses; it can be inferred that cleansing baths were a luxury only indulged in by the well-to-do. The bulk of the citizens relied on brimstone and treacle to ward off spring and heat spots, and scabies, which must have been pretty well endemic. After the repeal of the soap tax in 1853 bathing and bathrooms became more frequent and scabies less in those who bathed, so that a class distinction arose between those who bathed and those who did not, as in the present day. Doctors have never got, nor ever will get, any credit for prescribing common household remedies, especially if they carry a stigma with them. Sulphur cannot be disguised if taken internally; it always exhales the H_2S odour, so they just dropped it and applied it externally instead.

I wrote my first letter with the idea that it might be of some use as a war measure; preparations, however efficient and elegant, are not much use if they cannot be obtained owing to the war. I am not likely to be called on to treat scabies again, but if I am, whatever external treatment the patients have, they are going to have sulphur internally as well, just in case the first shot misses, and personally I always keep a few sulphur tablets by me in case I should be unlucky and pick up a wandering acarus.—I am, etc.,

H. M. BERNCASTLE.

Croydon, Oct. 3.

Treatment of Impetigo

SIR,—In reading the voluminous correspondence, I have been struck by the absence of mention of what I believe to be a safe, rapid, and certain cure of this disease. I refer to ultra-violet light locally administered. In this district, abounding in large schools, we have for many years treated epidemics of this disease, but since war began thousands of evacuees have come to the district, bringing infection to each other and to their unfortunate hosts and their families. Having treated literally hundreds of cases, I can only recollect one failure, where the scabs became so profuse that the parents refused to continue treatment owing to the unsightliness of the face.

Dr. R. T. Brain (October 4, p. 492) seems to me to bring out the whole object of the treatment, whatever form adopted, when he says: "Nature's defence against skin infection is the dry intact stratum corneum, and our treatment should be designed to maintain it." This ultra-violet light accomplishes to a nicety, the only essentials I lay down being that no ointments or other remedies be applied. It is essential to produce a mild degree of erythema, and all patients should be warned of this and assured that it will rapidly pass off in a few days. In some severe cases in middle-aged men fears were present of sycois barbae, so severe were the infections, but all cleared up rapidly under ultra-violet light. After the first dose dry scabs form in twenty-four hours; a second dose is then administered, which is usually sufficient, but in some severe cases a third dose may be necessary.—I am, etc.,

F. F. C. JAGGER.

Winchester, Oct. 6.

Treatment of Scabies and Impetigo

SIR,—The letters of Dr. Mumford and Dr. Brain (October 4, p. 492) contained very important points, and I would like to stress the undesirability of reporting "cures" for scabies which are based on far too limited an experience in the treatment of skin diseases. On the other hand, I cannot subscribe to Dr. Mumford's demand that the presence of living acarus must be shown before a diagnosis of scabies is tenable, and, conversely, that the absence of living acarus must be certain before cure can be accepted. This position is quite impossible where large numbers

have to be treated. Including children and adults and Service patients I see several thousands of cases annually, and I venture to say that Dr. Mumford's criteria of cure, while being no doubt the ideal, are, obviously impossible to achieve.

While not denying the almost universal experience of the large increase in scabies, I am certain from my own experience (and I have no doubt that other dermatologists would confirm this) that many cases of lichen urticatus and prurigo mites are included in cases of so-called scabies. This is obviously proved by the records of persistence of the lesions after apparently efficient treatment had been given. Cases of scabies so persistent should be referred to an experienced dermatologist.

There is no doubt about the value of benzyl benzoate in this disease, but sulphur is equally effective if properly used. The only advantages of the former are convenience and ease of application and much less risk of dermatitis, often mistaken for persistence of infection. Despite a recent paper in the *Journal*, I am convinced that infection from bed-clothes plays a great part in the spread of scabies, and the disinfection of these, along with the underclothing of the patient and inspection of contacts, forms an integral part of the proper treatment of the disease. Before the war the Liverpool city authorities treated scabies as a notifiable disease, and it was kept well under control. Under war conditions such a practice is not always possible, but it is the ideal at which to aim if control of the disease is to be achieved.

Dr. Brain's remarks were extremely valuable and should be pondered over by all called upon to treat cases of skin disease. Nevertheless, I feel sure that the merits of unguent, hydrarg. ammon. in the treatment of impetigo are much greater than is apparently admitted. This disease does not need the almost numberless remedies suggested for its cure. If the less common erythematous cases described by Dr. Brain are excepted, unguent, hydrarg. ammon. 2% will cure the great majority of the remainder. The probable cause of the mercurial dermatitis occasionally seen is that too strong an ointment has been used. I agree that where much serous exudation is present the first essential is to promote drying. Here gentian violet 1 to 2% is valuable, particularly if small exposures to ultra-violet light are added to the treatment. I have found cold starch and boric poultices to be most successful in the removal of scabs, and have often cured the disease without recourse to any other form of treatment. I have not had Dr. Brain's success with the use of soap and water; spread was so invariable that it is forbidden in my wards and clinics.

Finally, I am grateful for Dr. Brain's vindication of the use of sulphanilamide in the erythematous cases, where infection is more virulent. I have used this drug for several years with undoubted benefit. The dose need not be large—2 to 3 grammes daily—but the effect is gratifying. I have been told that such a dose could not be of use because the concentration of the drug in the blood would not be sufficiently high. My reply has been that for superficial skin infections this concentration need not be high, and I am glad of Dr. Brain's confirmation of this point.

—I am, etc.,

Liverpool, Oct. 9.

F. GLYN-HUGHES.

Scabies: Questionable Evidence of Cure

SIR,—On the subject of this very social disease, with two main exceptions there have been in your and several other columns recently many articles which seem to show a good deal of the modern expression "wishful thinking." The two notable exceptions have been from Dr. Kenneth Mellanby and Dr. P. B. Mumford. In order to substantiate the latter's letter (October 4, p. 492) I thought you might be interested in a few more actual figures.

Since January, 1940, I have been in charge of a hospital under the Ministry of Health for non-notifiable infectious diseases in evacuated children. As you would expect, a great many of these cases are of impetigo or scabies, or both. From January, 1940, to September 30, 1941, I treated seventy-five cases of pure scabies and twenty cases of scabies and impetigo. The children have all been admitted and not been returned home until considered cured. I have taken a cure to be no recurrence of signs or symptoms for fourteen days. This is, in all probability, too short a time, but economically has been found desirable at the moment. In these seventy-five cases only five have returned. Having these facts in mind, the average lengths of stay, using all known methods of treatment, are as follows: scabies alone,

seventy-five cases, 4½ weeks; scabies and impetigo, twenty cases, 6½ weeks. These figures include seven children removed by parents uncured.

The object of this letter is not to advocate any specific cure, but to show that even with children in a hospital for that purpose and treated by many different systems the average length of time for even theoretical cure is at least four and a half weeks in uncomplicated cases of scabies, and up to at least six and a half weeks in those complicated by impetigo. I do feel very strongly that anyone who claims a cure in much under this time (especially seven days) is suffering from not only "wishful thinking" but an inability to follow up the cases.—I am, etc.,

Hadlow, Kent, Oct. 7

JOHN B. MARSHALL.

SIR,—Two criteria may be employed in the determination of cure of scabies. One is based on the absence of live acari; the other depends on clinical cure and freedom from irritation for a period of a fortnight or longer from cessation of treatment. Both are valid, but in my view the latter is the more valuable and indeed the only practicable method where large numbers of patients are being treated.

A method of treatment which produces the complete relief from symptoms noted in my report, a relief which continued without recurrence for months afterwards, should surely be regarded as an effective anti-scabietic measure without the support of time-absorbing and presumably fruitless search for acari. Where sulphur inunction has been employed, the slight residual irritation which not infrequently results without a frank dermatitis developing rather complicates matters, but I have not observed subsequent dermatitis in the series of cases treated by benzyl benzoate.

The weakness of the live acari method under the social conditions existing in the areas where scabies is most rife lies in the possibility that the patient may become reinfected quickly, and that live acari may be discovered on him at any period after a short interval following treatment. Kenneth Mellanby's discovery of a carrier state, in which the person may remain without symptoms for an unspecified period, diminishes the usefulness of the live acari method. Since it appears that even nymphs may be transferred from person to person, who is to say that a particular example of immature or adult acarus detected on a person developed on him after the application of a parasiticide or whether it came from another untreated person? If this cannot be decided easily, then the value of the test is seriously impaired, unless it is employed solely on patients under strict supervision as in hospitals. The suggested venereal mode of spread exemplifies the possibilities of early reinfection following complete extirpation of all forms of the parasite by treatment.

Can Dr. P. B. Mumford (October 4, p. 492) produce evidence that live acari (or viable ova) persist on the body after benzyl benzoate treatment as thorough as that which produced the complete and persisting relief from irritation noted? His deduction from Kenneth Mellanby's discovery of acari on symptomless volunteers is surely not valid, inasmuch as Mellanby's observations (as so far published) were not made on patients rendered symptomless by an effective parasiticide.

The investigations of Kenneth Mellanby and his volunteers are worthy of the highest praise if they lead to the easier control of this disease, which, until recently, has been accorded scant attention by dermatologists and research workers.—I am, etc.,

Hereford, Oct. 8.

I. F. MACKENZIE.

SIR,—Dr. P. B. Mumford's letter (October 4, p. 492) regarding the necessity for keeping strict control when reporting cures of scabies is interesting; so are his remarks concerning "blindly accepting prejudiced concepts." While not overlooking the necessity for pathological confirmation, one might consider that present ideas are tending too much to the academic and theoretical. After all, provided the patient obtains benefit and relief, what matter to him the *modus operandi*?

To require proof of the absence of living acari before admitting a cure is surely going a little too far. Many of us have them dormant and doing no harm for all we know. Dr. Mumford must realize that we do not insist on a pathologist reporting a skin free from staphylococci before pronouncing a person free from boils, or a throat free from haemolytic streptococci before giving up treatment for tonsillitis.—I am, etc.,

NEVIL LEYTON.

Herpes Labialis after T.A.B. and Chemotherapy

SIR,—I read with interest the article by Major C. E. van Rooyen, Dr. A. J. Rhodes, and Captain A. Cameron Ewing (August 30, p. 298). I have given T.A.B. intravenously in doses of 0.25 c.cm. in cases of gonorrhoea treated with sulphapyridine and of non-specific urethritis treated with sulphanilamide. In some cases T.A.B. was given concurrently with the drug in question on the fourth or fifth day of administration; in other cases it was given four to eight days after completion of a six- or eight-day course of chemotherapy. The T.A.B. used in either event was the same, and the results stated below were obtained during the same season—that is, spring and early summer of this year.

My observations were as follows: Herpes labialis is very common following T.A.B. when this is given four to eight days after a complete course of sulphapyridine. Herpes occurring in these circumstances is always labial and nearly always affects the external mucous membrane of the lips as well as the skin. Herpes has not occurred when the T.A.B. was given concurrently with sulphapyridine on the fourth or fifth day of the course. Herpes has not been observed after T.A.B. in patients treated with sulphanilamide. These results conform with the clinical observations of van Rooyen and his associates, and in some measure amplify them.—I am, etc.,

Sept. 13.

F. RAY BETTLEY, M.D.,
Major, R.A.M.C.**Medical Statistics in Wartime**

SIR,—May I be permitted to reinforce your plea (October 4, p. 481) for the release of medical statistics. In addition to the fact that no Annual Review has been issued by the Registrar-General since 1938 and that we are still awaiting the long-promised Report from the Ministry of Health, no Quarterly Returns have been published by the Registrar-General since December, 1940.

How does one reconcile this statistical black-out in England with the continued publication of the Quarterly Returns by the Registrar-General for Scotland? Yet Scotland is as deeply interested in this war, as the last Return for June 30 indicates. From this return we can see that immediate measures must be taken to deal with, for instance, a serious rise in both infantile and maternal mortality. Sir Wilson Jameson has issued a timely warning that "local authorities and the medical profession must remain on the alert," but as you, Sir, point out, we cannot remain effectively on the alert unless we are well informed. If the statistics for England and Wales are held up for military reasons, let the authorities be democratically frank and tell us so. In that event, however, would it not be wise for similar measures to be taken in respect of the Scottish figures? If there is to be an eclipse let it be a total one.—I am, etc.,

London, W.4, Oct. 6.

RICHARD M. TITMUSS.

"Perfect Sight without Glasses"

SIR,—Your annotation (September 13, p. 383), together with the trenchant comments of Messrs. Seymour Philips and David Hardie (September 27, p. 459) on the published works on this subject by Bates and Benjamin respectively, seem fully to dispose of any claim to merit of the methods advocated by these gentlemen, and to answer my friend Dr. J. Parness's query as to whether such methods have the blessing of standard ophthalmological opinion. It is therefore pertinent to question the wisdom of Dr. Julian Huxley in affording prominence to these methods in his recent broadcast. The name of Dr. Huxley, as a scientist is deservedly a household one among the laity, who might easily attach undue weight to his words through the belief of certain of the more uninformed members that a scientist is a person competent to speak with authority on any scientific subject, and by reason of the credence attached to B.B.C. broadcasts. Doubtless Dr. Huxley had no intention of proffering treatment; yet out of his vast audience it is not improbable that there were some who would be impelled to consult the books of Bates and Benjamin. Since treatment of any condition cannot be efficient, except fortuitously, unless based on an intimate knowledge of the patient and the pathological process from which he suffers, it follows that a line of treatment delivered gently may be harmful. Consequently, topics touching upon the treatment of bodily dysfunction, however indirectly, should be avoided in broadcasting.

The case cited by Dr. Huxley (September 13, p. 389) to you, Sir, in which improvement in sight occurred in a patient treated unsuccessfully for thirty years by other methods, proves nothing. One cannot generalize as to treatment on the basis of a solitary case; any medical man can instance recoveries apparently conditioned by unusual, unconventional, or even bizarre means.

I am perhaps unduly critical of Dr. Huxley, as in the public interest the question might well have been omitted. But the question having been put Dr. Huxley was hardly justified in giving the subject the added stress of repetition in a subsequent broadcast, together with the citation of books of reference.—I am, etc.,

Withington, Manchester, Oct. 4. LESLIE BALLON, L.R.C.P.&S.Ed.

The Midwife's Title

SIR,—Many local authorities and voluntary organizations still fail to give midwives their correct and proper designation—that is, State Certified Midwife or the abbreviation S.C.M. Invariably correct use is made of the term State Registered Nurse and the abbreviation S.R.N. Why is not the midwife's title, which is of much older date, also used correctly?

Frequently in advertisements it is stated that applicants must "hold the C.M.B. certificate." Someone given to harsh opinions might say that the use of this phrase is a bad habit resulting from loose thinking. The advertisers mean that the applicants must be State Certified Midwives, but they don't say so. The Central Midwives Board awards three kinds of certificate: (1) the "first certificate" awarded to State registered nurses successful at the examination held at the end of Part I of the course of midwifery training; (2) the certificate of enrolment as a midwife awarded to candidates successful at the examination held at the end of Part II of the course of midwifery training; and (3) a Midwife Teacher's Certificate of proficiency in the art of training pupil-midwives. It is strange that no one seems to have an urge to refer to "G.N.C. Certificate" as synonymous with State Registered Nurse.

May I hope that in the future all advertisers for midwifery staff will "invite applications from State Certified Midwives," and that if they wish applicants to be general trained nurses as well they will express this by adding afterwards the words "who are also State Registered Nurses." I suggest that these words should come afterwards and not before, for the obvious reason that the legal right to practise midwifery arises from State registration as a midwife and not from State registration as a nurse.

While on the subject of titles may I commend to employers of midwives the desirability of adopting standard titles for various appointments in the midwifery service, for example:

For midwives practising in institutions: staff midwife, instead of staff nurse or staff nurse-midwife or midwifery staff nurse or maternity staff nurse, all of which are in current use; midwifery sister, instead of sister or maternity sister or maternity ward sister; midwifery sister-tutor; midwifery sister-in-charge.

For midwives engaged in domiciliary practice: municipal district midwife (or city or county midwife); district midwife and district midwifery sister in the case of the staff of voluntary organizations.—I am, etc.,

London, W.1, Oct. 9.

COMYNS BERKELEY.

Avoidable Disability seen in Recent Amputations

SIR,—It is true that despite the vast experience gained during the last twenty years with many thousands of cases, one still sees far too many bad amputation stumps. I am in complete agreement with the views expressed by Mr. W. R. D. Mitchell in your issue of September 27, and by reason of the fact that in all amputation cases the responsibility for securing a satisfactory end-result rests with the artificial limb maker, I hope that a short summary of the major difficulties experienced from the limb-fitting point of view will be of interest.

A recent analysis of 500 cases of above-knee and below-knee amputations fitted with limbs at ten centres throughout England shows that 88 suffered from varying degrees of flexion at knee or hip, and 73 had adherent scars.

Flexion Deformity and Superfluous Flesh.—Flexion at the hip or knee always causes difficulty to the limb maker, and sometimes involves considerable expense for the construction of special limbs. While it is true that it can be prevented by

splinting when the patient is in hospital, it is our experience that most of the trouble occurs in the three or four months after discharge. During this period the uninstructed patient spends most of his time in a sitting position, and flexion naturally develops. Mr. Mitchell rightly states: "The ideal stump is, of course, firm and tapering to the end, with rounded contours and a minimum of flabby tissue." Yet 80% of the cases sent to us for limb fitting have received no instruction in the preparatory treatment which can do so much to achieve this ideal condition. An amputation stump, as soon as it is healed and painless, should be kept tightly bandaged (renewed night and morning), and exercised progressively by means of an elastic exerciser. This simple treatment, correctly applied, can in six weeks greatly reduce the superfluous flesh, retain full movement, and recondition the muscles. A patient who has received this treatment is far easier to fit with an artificial limb, and can control the limb and learn to walk well in a far shorter time than is necessary with a patient who has had no preparatory treatment. This means an earlier return to work and less subsequent trouble.

Adherent Scars.—The best results with artificial limbs are obtained when it is possible for the patient to control the limb and walk purely by movement of the stump. The primary function of the stump is weight-bearing, but as weight is applied and relieved it causes a slight piston action between the stump and the socket, and this pulls the skin over the end of the bone. An adherent scar is therefore always a great disadvantage. The practice of using equal lateral skin flaps in amputations below the knee not only places the scar at the maximum point of pressure in relation to the socket of the artificial limb, but also nearly always results in the scar becoming adherent to the end of the tibia. This very often means that a looser fitting must be given and weight-bearing must be taken by an extended thigh corset having a bearing on the tuberosity of the ischium—a less comfortable limb with increased disability.

Excessively Long Stumps.—In the cases referred to above, quite a number of above-knee cases had stumps over 11 in. long, but a much larger proportion of the below-knee cases had stumps over 7 in. long. It is curious that too long a stump should be more frequent in below-knee cases than with above-knee cases, but apparently the practice of amputating just above the ankle for foot injuries is still fairly common. The disadvantages of long stumps are well known and can be briefly listed: (1) bad circulation, leading to breakdown; (2) impossibility of constructing the artificial limb to obtain correct alignment or to match the sound limb, also increased bulk and weight; (3) no space for a modern knee mechanism, and therefore bad gait.

Guillotine Amputations.—Whatever may be the surgical advantages of guillotine amputations, it is most certainly an amputation that the limb maker would far prefer never to see. From a practical point of view it appears wrong to cut straight through a limb and then by traction to try and stretch an inadequate amount of skin to cover the end of the stump; in practice it always results in a large area of adherent scar tissue, causing great difficulties in limb fitting. It is rare that a fully satisfactory result is obtained.—I am, etc.,

London, Oct. 1.

Director, Desoutter Brothers, Limited.

The Tellurite Medium of Wilson and Blair Selective for *B. dysenteriae* (Flexner)

SIR.—The article by Prof. W. J. Wilson and Dr. Blair, published in your issue of October 11 (p. 501), is a welcome contribution on an important problem which has hitherto presented much difficulty apart from Leifson's work. It may be of interest to your readers to know that as the result of extensive work I can confirm the effect of the addition of tellurite to medium for suppressing the ordinary coliform organisms, while permitting the Flexner types of dysentery bacilli to flourish. A further striking character of media containing tellurite is that they also permit the growth of *B. dysenteriae* (Shiga), as I have found in a study of thirteen strains (none of which, unfortunately, was very recently isolated). Thus tellurite media may prove of great value in the diagnosis of dysentery of Middle European and tropical origin.—I am, etc.,

Obituary

JAMES KERR, M.A., M.D., D.P.H.

Consulting Medical Officer, L.C.C.; formerly School Medical Officer for London

The death of Dr. James Kerr on October 5 at his home in Regent Terrace, Edinburgh, removes a pioneer whose enterprise and vision in the early years of this century, when he was school medical officer for London and the mainspring of an enthusiastic group of workers, established the value of school hygiene as a necessary public service, after he had originated the school medical service in Bradford.

James Kerr was born in Glasgow, and from Manchester Grammar School entered St. John's College, Cambridge, with a science scholarship. He gained first-class honours in the Natural Sciences Tripos of 1883, and followed this with a senior science scholarship at St. Bartholomew's Hospital. He took the M.B., B.Ch. degrees and the D.P.H. of Cambridge in 1887, the M.A. in 1888, and the M.D.

in 1891. Beginning his career with clinical ambitions, he was elected to the honorary medical staff of the Bradford Royal Infirmary and the Bradford Eye and Ear Hospital after some experience in general practice, and turning later to administration was made medical superintendent under the Bradford School Board, and organized with great success the school medical service of that city. He came to London as the first medical officer to the old London School Board, and on its absorption by the L.C.C. became Medical Officer (Education), and held that post with great distinction from 1902 to 1911, publishing valuable papers and reports on school hygiene and kindred subjects. Throughout his administrative work he retained the outlook of the clinician.

Among many other public duties Dr. Kerr undertook the secretaryship of the second International Congress of School Hygiene, served on the International Commission on Standards of Illumination, and was a member of the examination board and chief examiner in hygiene for the English Board of Education. He gave the Ingleby Lecture before the University of Birmingham, and was awarded the Howard Medal by the Royal Statistical Society. During the last war he held a commission as temporary major in the R.A.M.C., and was honoured by the rank of Officier de l'Instruction Publique de France. He published two small books, one entitled *The Air We Breathe* and the other *School Vision and the Myopic Scholar*, and in 1926 a large and important work, *The Fundamentals of School Health*. The last-named publication filled a gap in medical literature: it was the outcome of patient recording and checking of accumulated facts during many years. In writing its 850 pages Dr. Kerr gathered up his experience and followed it to the present-day development of an established system of health culture in childhood and adolescence the like of which had never before been seen. The book is a mine of information on every side of health and disease in relation to school life, with abundant references to original literature. Its practical purpose, well fulfilled, was to help everyone concerned in education to secure better and better conditions for the children. It set forth all the known facts upon which to found a scientific study of the hygiene of the growing age.

Dr. James Kerr joined the British Medical Association in 1889. He was a member of the Fabian Society for many years, and served on its executive for a time; he was also a member of the Labour Party's Advisory Committees on Public Health and on Education. Taking up residence in Edinburgh after his

retirement twelve years ago, he became chairman of Donaldson's Hospital, and took a close interest in the work of that institution on behalf of the deaf and dumb. He is survived by his wife and by his son, Dr. Douglas Kerr, principal police surgeon under the Corporation of Edinburgh.

ROBERT BRIGGS WILD, M.Sc., M.D., F.R.C.P.

We regret to announce the death at Buxton on October 7 after a long illness of Dr. R. B. Wild, emeritus professor of materia medica and therapeutics in the University of Manchester.

Robert Briggs Wild was born at Holcombe, Bury, in 1862, the son of the late Robert Wild. His scientific education was received at Owens College, Manchester, and he won prizes, scholarships, exhibitions, and medals during his student career. He graduated B.Sc. (with honours in physiology) at the Victoria University in 1883, and in the intermediate M.B. won a gold medal and exhibition in the same subject. His M.D. (1887) was also passed on gold medal standard. He actually qualified in 1884, before obtaining the London M.B. in 1886, with the L.S.A. diploma, a favourite way in the first instance of earning the means to reach higher professional steps. The M.R.C.S. followed in 1885. He proceeded M.Sc. Vict. in 1894. After residence in the Manchester Royal Infirmary as house-physician he began practice in 1886 and, taking a special interest in pathology, was appointed as registrar in this subject at the hospital and for many years carried out all the necropsies himself and demonstrated their lessons. At the same time he assisted Julius Dreschfeld in lecturing on pathology, a chair of which had been established at Owens College as the first of its kind in England (1881). Wild was keenly interested in the work and was a very good teacher, clear, precise, and definite. He helped Dreschfeld in no small way to prove the importance of pathology in medical education and in having it made a subject for the Manchester medical degrees. Other examining boards followed suit. After this pathological work he joined Daniel John Leech in the materia medica and therapeutics department, lecturing and developing the experimental pharmacology laboratory, of which both Leech and he were enthusiastic supporters. Several men obtained their doctorates by research in this laboratory, Wild's scientific mind assisting them greatly in their work. He also was very helpful to Leech in the investigation of the action of the nitrites on the circulation and in getting amyl nitrite made an official preparation. On the death of his chief he succeeded to the chair, which was endowed as a whole-time office by Leech.

Wild was elected an F.R.C.P. in 1912 and was an examiner for the college for four years. He was also for some years dean of the Manchester Medical School and a prominent member of its Faculty with very definite ideas on the medical curriculum. For a time he acted as Pro-Vice-Chancellor of the University, and in later years represented it on the General Medical Council from 1922 until his retirement from Manchester in 1927. He naturally took much interest in scientific discussions and was president of the medical and pathological societies of the city. He also founded one for therapeutics alone, but it died in early infancy from neglect and inanition. Though he had a very good knowledge of general medicine and of the various methods of treating disease, Wild's chief consulting practice was in diseases of the skin, and he was the leading authority and teacher in the city after the death of H. A. G. Brooke. The Manchester and Salford Hospital for Diseases of the Skin was opened in Dale Street as a separate institution from the Lock and Skin Hospital, for the sole treatment of diseases of the skin. Walter Whitehead was the chief actor in this desirable divorce, and one of his junior colleagues helped him for a few months in 1892 in seeing the patients. Wild's name was then suggested as an assistant, and this being agreeable he saw all Whitehead's cases in an unofficial capacity until he was elected honorary assistant physician in 1894. For many years he was the mainstay of the Christie Cancer Pavilion and Home which was founded in 1882 with this title, subsequently changed to that of the Christie (Cancer) Hospital and Home. He took the physician's side of the treatment and played a very active part in the administration of the hospital. He tried every medical remedy with a reputed action for good on cancer that was suggested to the hospital.

He found, however, that few had any value in relieving pains and distress, let alone curing the disease. He wrote many papers on the actions and uses of medicines and on diseases of the skin, including cancer.

Prof. Wild was a member of the British Medical Association for thirty-eight years, and at the Annual Meeting in Manchester in 1902 he served as vice-president of the Section of Pharmacology. In 1909, at the Belfast Meeting, he was vice-president of the Section of Dermatology and Electrotherapeutics; at the London Meeting in 1910 he was vice-president of the Section of Dermatology; and at Bath in 1925 he held office as president of the Section of Therapeutics. He served on the Standing Therapeutics Subcommittee of the Association in 1919-21.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Titles of the degrees of M.B., B.Chir. were conferred by diploma during September on J. I. Hallinan of Girtton College, and on J. W. Shrimpton of Newnham College.

J. Morton has been approved at the examination for the Diploma in Medical Radiology and Electrolgy (Part II).

Vice-Chancellor's Valedictory Address

At a Congregation of the Senate held on October 1 Mr. E. A. Benians, Master of St. John's College, resigned the office of Vice-Chancellor, and Dr. J. A. Venn, President of Queens' College, was admitted as his successor for the year 1941-2. In the course of an eloquent address Mr. Benians gave a survey of the second year of war in its relation to the academic life of Cambridge, and recorded benefactions, losses by death, and the departure on national service of many university officers. He spoke of a Christmas message from the Universities of Harvard and Yale expressive of the bonds of friendship that unite the two countries and of the common ideals and traditions shared by English and American scholars, adding his own plea for a new consideration by the History Faculty of the educational value of American history. Coming to the general administration of the University he noted the heavy burden caused by depletion of staffs during a year of full activity in which no essential function had been suspended. The many calls made upon accommodation in Cambridge had strained resources to the utmost, and he doubted if university and college buildings had ever been more fully used. Emergency regulations, the absence of many teachers, the addition of special courses, adjustments and readjustments of many arrangements, had imposed a continuous strain on the central administration. Work on new buildings and the reconstruction of old ceased with the outbreak of war, and only what was necessary for the wartime protection of buildings had been undertaken. With regard to the educational activities of the year Mr. Benians said that the decision of the Government that the continuance of university education was essential to the present and future interests of the nation was a call to maintain work to the best of everyone's powers. The results of the examinations showed no falling off in the quality of students' work. With a grateful acknowledgment of the help given him from all sides he said, "Looking back on the two years of war which have now passed—years in which we have been so closely occupied with urgent business as to have little time for general reflection—I see the University finding its place in the national effort. I see, too, the growing recognition in all quarters of the importance of the universities as schools of character and schools of professional training, and none who have followed the trend of events in the last two years can fail to see that great tasks will be laid upon them when peace returns. Universities have long ceased to be the forefront of modern life; more and more it is realized that education, learning, and research are the root of national effort and not merely a splendid efflorescence. . . . The universities will have a great part to play in repairing the national loss. Commerce and industry, as well as education and the public services, will, I believe, look more and more to the universities for men of character and ideals, and connexions made in time of war must not be abandoned in peace. We have to bring our science into close and fruitful contact with industry and administration and to send forth chivalrous leaders into industrial life and fit teachers into all the fields of education. The Empire over-seas will make great claims upon us. Thus, while we give all assistance we can to every side of the national effort, it remains vital, for the sake both of present and of future needs, that we should also keep in efficient being the great educational

institutions of which we are at the moment the guardians. We talk of our own affairs, but it is the common task and the common peril that press upon us. History knows no such scene as that in the midst of which we contend to-day, nor was ever more at stake. The pursuit of truth and the dominion of reason are the articles of our faith. All that is ennobling in man's long struggle issues from them. Yet, if freedom perish, they will perish."

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a recent meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, the President, Mr. Roy F. Young, in the chair, the following were admitted Fellows of Faculty: James Walker Ferguson, M.B., Ch.B., Hector Ross MacLennan, M.D., M.R.C.O.G., Thomas Semple, M.B., Ch.B., Harry Ellis Charter Wilson, D.Sc., M.B., Ch.B.

Medical Notes in Parliament

Post-war Hospital Policy

Sir FRANCIS FREMANTLE on October 9 asked the Minister of Health whether he was in a position to indicate the general lines of the Government's post-war hospital policy. Mr. ERNEST BROWN, in reply, made the following statement:

The question of post-war hospital policy and reorganization, more particularly in relation to the Emergency Hospital Scheme, has for some time been engaging the attention of the Government. While any immediate reorganization must be regarded as impracticable in present circumstances, certain broad principles can be laid down as the basis of Government policy.

It is the objective of the Government, as soon as may be after the war, to ensure that by means of a comprehensive hospital service appropriate treatment shall be readily available to every person in need of it. It is accordingly proposed to lay on the major local authorities the duty of securing, in close co-operation with the voluntary agencies engaged in the same field, the provision of such a service by placing on a more regular footing the partnership between the local authorities and voluntary hospitals on which the present hospital services depend. The Government recognize that to achieve the best results and to avoid a wasteful multiplication of accommodation and equipment it will be necessary to design such a service by reference to areas substantially larger than those of individual local authorities. It will be the aim of the Government also to avoid overlapping and uneconomical expenditure by securing the provision of the more highly specialized services at teaching hospitals and other centres selected to serve these wider areas and by arranging for a proper division of function between hospitals in these areas.

With regard to the financial aspects of the Government's proposals, it is their intention to maintain the principle that, in general, patients should be called on to make a reasonable payment towards the cost, whether through any contributory schemes or otherwise. In so far as any new burden may be thrown upon local authorities in providing or maintaining hospital accommodation, or in contributing towards the expenditure of voluntary hospitals, a financial contribution, the extent of which will be a matter for further consideration, will be made available from the Exchequer. Special arrangements for dealing with the teaching hospitals by way of increased educational grants are in contemplation.

In present circumstances the arrangements for hospital services must be determined by wartime requirements, but the Government are anxious to take every step to avoid any unnecessary delay. I have already had preliminary discussion with the bodies representing the municipal hospital authorities and the voluntary hospital movement, and I am hopeful that these discussions will be continued. With their concurrence I am instituting a survey of hospitals in London and the surrounding area to provide the information needed as a basis for future plans. As regards the remainder of the country, valuable preliminary work has already been done in some areas by bodies representing both the municipal and voluntary hospital authorities, in particular by an organization formed under the auspices of the Nuffield Provincial Hospitals Trust. In any surveys which it may be found necessary to institute in the Provinces, I shall have full regard to

the information already available in this way, which I am glad to know will be at my disposal for the purpose.

I am asked by the Secretary of State for Scotland to take this opportunity of stating that the aims of future policy in Scotland are generally similar, but that certain important differences in the Emergency Hospital Service and in the methods of financing voluntary hospitals in Scotland are being given special consideration.

Sir FRANCIS FREMANTLE asked if the survey would be carried out simply by the officials of the Department concerned or if officials of the local authorities would be consulted along with professional or other outside persons who were interested. Mr. BROWN replied that he would do his best to see that the most competent persons were consulted, including local bodies.

Asked by Dr. HADEN GUEST if he would consider hospital policy in relation to the future of the medical profession as a whole, with a view to bringing forward a scheme for a general health service in the country, Mr. BROWN stated that that was a wider question, and the hospital service must be considered first. The Minister also said that the general control to be exercised by his Department would secure that in the design of the scheme for the future hospital service full opportunity would be given to the voluntary hospitals to play their part.

Invalids' Special Rations

On September 30 Major LLOYD GEORGE circulated the following table of weekly supplementary allowances of rationed foods for invalids:

Disease	Supplementary Allowance		Coupons to be surrendered
	Food	Quantity	
Diabetes	Butter and margarine	12 oz. (not more than 4 oz. butter)	Sugar
	Meat	2s. 4d. adult, 1s. 2d. child under 6	
Diabetes—vegetarians only	Cheese	8 oz.	Sugar
Hypoglycaemia	Sugar	16 oz.	Butter and margarine
Steatorrhoea	Meat	4s. 8d. adult, 2s. 4d. child under 6	
Nephritis with gross albuminuria and gross oedema; also nephrosis	Meat	3s. 6d. adult, 1s. 9d. child under 6	—

Lord Woolton's medical advisers are of opinion that, provided adequate supplies of vitamin C are available, there is no need for a special supply of oranges for anyone suffering from any disease or injury. Major Lloyd George could not adopt a suggestion that, during the children's priority period or immediately after, oranges should be made specially available to invalids, and that the special requirements of tuberculous patients should be recognized.

Orthopaedic Treatment in Scotland

Mr. TOM JOHNSTON gave an assurance on October 1 that the six new orthopaedic units in Scotland were on the lines recommended by the Delevingne Committee. There were ten orthopaedic surgeons, of whom four were employed whole-time. The junior staff consisted of one junior surgeon, who acted as registrar in each of the units except Peel Hospital, Selkirkshire. Other junior staff were attached to each unit by the medical superintendent up to three per 200 beds.

Home Guard Medical Officers

Mr. ERNEST BROWN explained on October 1 that to avoid undue interference with the medical organization of the locality Army Council instructions provided that no medical practitioner was to be enrolled in the Home Guard unless previous permission had been given by the Local Medical War Committee. It was open to any practitioner aggrieved by the Committee's decision to communicate with the Central Medical War Committee, under whose general directions the local committees acted in this as in other matters relating to the selection of doctors for wartime services. If dissatisfied with the conclusion of the central committee the practitioner could make representations to Mr. Brown, who would be prepared to consider them. There was no representative of the Home Guard as such in the central committee, but an observer attended on behalf of the War Office.

Diet of Workers in Heavy Industries

Mr. JAMES GRIFFITHS opened a debate on October 2 about food distribution, and dealt with the special needs of miners and steel workers of South Wales. Prof. A. V. HILL said the man who worked at a level of 6,000 calories a day could not remain healthy and contented on the same diet as the sedentary worker plus extra bread. He needed at least one-fifth of his energy in the form of fat and must have 2½ lb. of fat weekly. That was impossible on the present ration. Vitamins could not replace energy in the diet of heavy workers.

Major LLOYD GEORGE said the nation was better off for staple foodstuffs than last year or, in some cases, than before the war. He hoped that by mid-November a scheme would be introduced for the fair distribution of unrationed commodities. The Government did not propose to alter its policy of giving the maximum ration to all consumers rather than a supplementary ration to particular classes at the expense of the community. They had encouraged the setting up of canteens and British Restaurants, and would increase food supplies to transport cafés on the main roads. Canteens for mine workers were being provided more rapidly. For all canteens in a first priority category, to be decided in consultation with Mr. Bevin, the Ministry of Food hoped to double the meat ration, to treble the sugar allocation, and to increase the allowance of cheese. Announcements would soon be made on school feeding.

Sir E. GRAHAM-LITTLE said the effort to popularize the national wholemeal loaf had not been highly successful. Compulsion would have effected an immediate result. The wholemeal loaf was not in general supply, and for fourteen months the nation had fed on an inefficient and fallacious diet.

Dr. EDITH SUMMERSKILL said Lord Woolton should direct his attention to the fact that pulmonary tuberculosis, which often resulted from under-nourishment, was increased in this country, particularly in the age groups between 18 and 40. Expectant mothers working in factories should have equal consideration with those who were doing heavy manual work. Major LLOYD GEORGE promised close attention to the points raised in the debate.

Diphtheria Immunization

Replying on October 2 to Mr. W. Leach, Mr. ERNEST BROWN said immunization of children against diphtheria necessitated two, or at most three, injections of the prophylactic. It was considered that immunity, once established, persisted for years and perhaps for life. Inoculation was carried out only with the written consent of the parent or guardian of the child. The Ministry of Health did not accept responsibility for any mishap arising out of inoculation.

Rehabilitation of Disabled Persons

Mr. ERNEST BEVIN, in answer to Sir Francis Fremantle, said the Ministry of Labour had started the interviewing of disabled persons in hospital, in conjunction with the hospital authorities. A leaflet had been prepared which described the interim scheme for resettlement and training of disabled persons. He was consulting other Departments in order to develop a wider national scheme.

On October 2 the Minister stated that circulars had been sent to hospital authorities setting out arrangements for treatment, rehabilitation, and subsequent training of fracture cases. Patients had been successfully treated at centres which had been in operation for some time, but statistics were not available.

Mustard Gas Decontamination

On October 9 Mr. GROVES asked the Parliamentary Secretary to the Ministry of Supply whether he had yet received the report of the re-examination of a basic pharmaceutical ingredient consisting of a dehydrated calcium hypochlorite admixed with a dehydrated sodium perborate; and whether the results of the examination disclosed that such product was an effective decontaminant of the eye from mustard gas. Mr. H. MACMILLAN said that several reports on the mixture referred to had been received. They showed that it was not an effective decontaminant for the eye after contamination with mustard gas.

The Services

NAVAL AWARD

The D.S.C. has been awarded to Surgeon Lieut. Eric Arthur Penn, R.N. (H.M.S. *Ladybird*), for courage and coolness when his ship was sunk by enemy aircraft.

R.A.F. COMMENDATION

The King has ordered the publication of the name of Flying Officer Frederick Alastair Forbes, R.A.F.V.R., as having received an expression of commendation for brave conduct in connexion with civil defence.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL ARMY MEDICAL CORPS

Wounded

Colonel Cyril Popham.
War Substantive Captain Edward Alexander Robertson.

SOUTH AFRICAN MEDICAL CORPS

Lieut.-Colonel JOHN GERALD McMENAMIN, the eldest son of Mr. J. J. McMenamin of Capetown, died on active service in Abyssinia in April. He received his medical education at St. Bartholomew's Hospital, London, and qualified M.R.C.S., L.R.C.P. in 1924. For some years he was honorary assistant physician at Germiston Hospital, Transvaal.

Medical News

Prof. R. R. Macintosh will deliver a lecture on "Anaesthetics in Wartime" at the Weston Hotel, Bath, on Thursday, October 23, at 5.30 p.m. All Service medical officers and civilian practitioners will be welcome.

The first scientific meeting of the Nutrition Society, the formation of which was announced in our last issue at page 521, will be held at the Physiological Laboratory, Downing Street, Cambridge, to-day (Saturday, October 18), beginning at 11 a.m. Buffet lunch and tea will be provided.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, October 23, at 4.30 p.m., when Dr. T. Christie will read a paper on "The Manic-depressive Psychoses (in Relation to the Crime of Murder), with some Medico-Legal Points."

At a meeting of the Leeds and West Riding Medico-Chirurgical Society held on October 3 Dr. A. Massey, C.B.E., Medical Officer of Health for Coventry, gave a lecture on "Emergency Hospital Work—Coventry Experiences."

A war memorial fund is being formed in memory of the four staff masseuses who lost their lives when St. Thomas's Hospital was bombed in September, 1940. Donations should be sent to: Miss M. Randell, C.S.M.M.G., Massage School War Memorial Fund, St. Thomas's Hospital, S.E.1.

Dr. James Macfarlane of the Department of Health for Scotland has been appointed medical liaison officer at the Scottish Office, Fielden House, London. He will maintain liaison with the Ministry of Health and medical branches of the Services Departments and other Government Departments located in London.

At the invitation of Dr. H. Lightstone, the Director-General of Medical Services, Ministry of Pensions, a conference of the orthopaedic surgeons attached to the Ministry of Pensions hospitals was held at Queen Mary's Hospital, Roehampton, from September 24 to 26. Mr. G. R. Girdlestone, honorary consultant to the Ministry, presided. Demonstrations were given in the wards by Mr. George Perkins and Mr. T. Pomfret Kilner, and in the limb-fitting centre by Dr. A. Kelham and Captain Maxwell. Lieut.-Commander J. Bunyan, R.N.V.R., by permission of the Admiralty, showed a cinematograph film illustrating his method of the treatment of burns and other injuries by irrigation envelopes, and demonstrated a number of cases treated in this manner (see *British Medical Journal*, July 5, 1941).

No. 39

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended September 27.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1941					1940 (Corresponding Week)

* Includes paratyphoid A and B for Northern Ireland.

† Includes primary form in figures for England and Wales, London (administrative county), and Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

With the exception of whooping-cough, notifications of the common infectious diseases in England and Wales were larger than in the preceding week. An increase of 133 cases of measles marks the end of the continuous decline in the incidence of this disease, which had extended over seventeen weeks. During this period the notifications fell from 13,400 to 612 per week. The rise in the number of cases was mainly due to the large increase shown by two counties—Lancashire, where the cases rose from 95 in the preceding week to 132; and Staffordshire, where the cases increased from 69 to 147 (Walsall C.B. 6 to 55).

The rising trend of diphtheria continued both in England and Wales and in Scotland; the number of cases is the largest for any week since March. The increased incidence in England and Wales is still chiefly confined to Cheshire, Lancaster, and Yorkshire. Although the totals for the past two weeks are below those of the corresponding weeks of last year, the rate of increase is the same for the two years. The total number of cases reported in the last four weeks is 1.3 times the total in the preceding four weeks. Glasgow, with 107 notifications, contributed over one-third of the cases reported in Scotland.

There were 118 cases of scarlet fever in excess of the total of the preceding week in England and Wales. During the past two weeks the disease has shown an increase of 25% in the number of notifications. Another small rise was reported from Scotland, where the weekly notifications have been doubled since the beginning of August. In Scotland an increase of 3 on last week's total was recorded for dysentery. The chief outbreaks were in Dundee 16, Edinburgh 8, Lanark County 19, and Glasgow 13. No outbreak of any size occurred in England and Wales, and the total was 13 less than in the preceding week. The notifications of paratyphoid declined by 25 in England and Wales.

Poliomyelitis

After the relatively large decline recorded in the previous week in England and Wales, from 36 to 28 cases, the notifications for the week reviewed rose to 38, the largest recorded this year. Five cases were notified in the counties of Berkshire (Maidenhead M.B. 2, New Windsor M.B. 2, and Reading C.B. 1) and Oxfordshire (Oxford C.B. 4 and Bullington R.D. 1). In administrative areas multiple cases were recorded in Hertfordshire (Hatfield R.D. 2); Lancaster (Manchester C.B. 4); Middlesex (Southall M.B. 2); Norfolk (Norwich C.B. 2). The cases notified in Scotland were Edinburgh 2 and Glasgow 2.

Week Ending October 4

Cases of infectious diseases notified in England and Wales were: scarlet fever 1,217, whooping-cough 2,078, diphtheria 997, measles 715, cerebrospinal fever 109, poliomyelitis 31, dysentery 108, paratyphoid 87, typhoid 34. Fourteen deaths were attributed to influenza, the largest number for nearly four months.

S. H. Gurian (*Arch. Pediat.*, 1941, 58, 528), who records a personal case, states that during the six-year period January 1, 1935, to December 31, 1940, there had been only one case of accidental transmission of malaria among approximately 3,500 transfusions given at the Flower and Fifth Avenue Hospitals, New York, located in an area densely populated by Puerto Ricans. The rarity of malaria accidentally transmitted by transfusion is also shown by the fact that there are only thirty cases on record, including the first reported by Woolsey in 1911. Gurian attributes this low incidence to the following factors: (1) the presence of antibodies in the blood of a malarial individual; (2) the transfer of these antibodies from donor to recipient; (3) the relatively low concentration of parasites in the blood of an adult donor; (4) the use of small-volume transfusions and the practice of small-volume blood-letting. Gurian's case was that of a girl aged 2½ who was treated for severe nutritional anaemia by transmission of blood from a man aged 21 years who had had malaria in Puerto Rico at the age of 6. Numerous quartan plasmodia were found in the child's blood. Recovery took place under quinine treatment.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Attitology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Brittle Nails and Chilblains

Dr. FRANK MATTHEWS writes: Could anyone advise me as regards diagnosis and treatment in this case? A married woman aged 42 has suffered from very thin and brittle nails of fingers and toes for four years. She usually feels cold and has chilblains; no arteriosclerosis, no focus of infection discovered. She has had long courses of kalsana, osteo-calcium, collosol calcium, and ultra-violet rays, with no improvement.

Chronic Congestive Condition of Hands

"STASIS" writes: I should be glad of any advice on a complaint from which I (a woman doctor myself) am a sufferer: a chronic congestive condition of both hands, the skin being always blue and cold, more so during the winter, when chilblains tend to develop. The feet are not involved, and otherwise I have excellent health. In addition, small subcutaneous haemorrhages occasionally appear on slight pressure, say, when turning a door handle, etc. I have taken calcium in various forms over a long period, with halibut-liver oil, etc., but so far the only remedial agent which has given benefit (only temporary) is sunlight applied to the hands. Any further suggestion would be gratefully appreciated.

Tenosynovitis

Dr. E. T. LARKHAM (Birmingham) writes: Captain A. A. Williams (September 13, p. 377) will find the application of empl. ammoniaci c. hydrarg. (B.P., 1898) spread on thick material most efficient in tenosynovitis; in some acute cases the relief is immediate.

Income Tax

Practitioner in R.A.M.C.

P. B. carried on his practice until the end of May, 1940, when he joined the R.A.M.C. His practice is apparently being carried on under the normal emergency arrangements. He is assessed for 1940-1 on the basis of the profits of the practice for 1939-40. Is this correct?

** Yes. The legal position appears to be that the practice has not ceased but is being carried on by practitioners acting as the agents of the practitioner. The appropriate remedy against hardship is to claim under the section providing relief in respect of diminution of earned income (Finance Act, 1940, Sec. 23) if the 20% condition is satisfied.

Schedule E: Basis of Assessment

R. acted as house-surgeon from July, 1937, to January, 1938, then took an appointment as assistant to a general practitioner, but returned to house-surgeon's work from March, 1939, to September, 1940, after which he became an A.M.O. to a local authority. Can he claim the previous year's basis for 1941-2?

** No. There is no legal claim to adopt the previous year's basis after a change of employer, unless the case falls within Section 26 of the Finance Act, 1935. One of the conditions laid down in that provision is that the change does not result in an increase of more than 20% in the emoluments, and that condition bars any claim by R. R. The Inland Revenue authorities do make some concession with regard to changes, but the dissimilarity between the nature and emoluments of R. R.'s appointments in 1940-1 and 1941-2 is such as to place his case outside that concession.

LETTERS, NOTES, ETC.

A Case of Idiosyncrasy to Strychnine

Lieut. P. R. SAVILLE, R.A.M.C., writes: The following unusual case of idiosyncrasy to strychnine may be of interest to your readers. I recently prescribed a tonic for Lieutenant A—a simple iron and strychnine mixture, each dose containing 3 minims of tinct. nucis vom. The patient took one dose, and in fifteen minutes his face flushed, he had headaches, with beads of perspiration, and the palms of his hands itched. He felt very faint and "almost collapsed." He recovered in half an hour, and came to see me later on with no ill effects other than headache. His first words were: "Was there any strychnine in my medicine?" Apparently, in 1934 his doctor prescribed a similar medicine with "not sufficient strychnine in it to harm a baby." He then had a similar group of symptoms, even more severe, and lost consciousness for ten minutes. His doctor at the time told him to avoid strychnine in the future; he omitted to tell me this. The whole of the medical inspection room staff, including myself, took doses of the same medicine and showed no ill effects.

Cost of Diphtheria Immunization

Dr. OWEN WILSON (Nelson) writes: A week or two ago I heard an eminent medical broadcaster announce on the B.B.C.'s home transmission that "a child could be protected against diphtheria at a cost of 7½d." I looked up a manufacturer's price-list, and found one 0.5 c.cm. dose of A.P.T. listed at 2s. 6d. Many parents who choose to have their children treated by their own doctor must have got the impression that they are grossly overcharged. If the B.M.A. has any useful function it ought to deal with questions like this.

Radiographs of Tuberculosis Workers

Dr. ROSE JORDAN writes from Uckfield, Sussex: On retiring, after twenty-five years' service as tuberculosis officer, I thought it would be of interest to see the radiological pictures of myself and my staff, six of whom had worked with me, in close contact with tuberculous patients, for periods extending from seven to twenty-one years. The results showed that, while in two of the radiographs minute calcareous deposits could be seen, the remaining five showed no radiological changes whatever in the lungs. Perhaps this demonstration may be of encouragement to lay workers in the field of tuberculosis.

Surplus Copies of the Journal

The restricted consumption of paper now permitted by the Paper Control of the Ministry of Supply makes it imperative that the margin between the number of copies of the *British Medical Journal* printed each week and the number required for immediate dispatch be maintained at the lowest possible figure. With the tendency to an increased circulation brought about by the war, a number of the earlier issues of 1941 are now out of print. The publishing department would therefore be grateful for any unwanted copies, particularly those published in the first three months of this year. Copies should be sent, carriage forward, to the Secretary of the Journal Board, B.M.A. House, Tavistock Square, London, W.C.1.

A Newspaper's Inquiry

Dr. E. STARLING writes: I administered an anaesthetic to one of my patients who was being delivered by a midwife. On the following morning I was rung up by a provincial newspaper office and asked to confirm the birth of the child. I demurred somewhat sharply, on the grounds of professional secrecy, but was told it was "our usual custom." I subsequently found out that the father, who called at the office in person to insert a notice in the birth column, had been asked to give my name and telephone number as well as those of the midwife. I believe that finally the mother herself was called upon to confirm the announcement. I imagine that a patient's condition after delivery is as much a matter of confidence as it is during pregnancy, and I should be glad to know whether other practitioners have had similar experiences. Neither my partner nor myself has ever been approached in this way before.

Operability of Carcinoma of Rectum: Corrigendum

We wish to correct a printer's error which occurred in Mr. J. C. Goligher's article in our issue of September 20. In line 21 of the second column on page 394 the phrase "while 94 had apparently inoperable growths" gave an entire reverse of the author's meaning. The sentence should have run: "While 94 had apparently operable growths, in which confirmation of operability at laparotomy was precluded, etc."

OBSERVATIONS ON THE CEREBROSPINAL FLUID IN CLOSED HEAD INJURIES

BY

J. W. ALDREN TURNER, D.M., M.R.C.P.

Neurologist. E.M.S.

These observations are based on the study of 85 patients who were admitted to an E.M.S. head injury centre within a few days of an injury from which no open wound of the skull had resulted. Most of the patients were involved in motor-cycle or lorry accidents, but some were air-raid casualties who had been thrown to the ground or hit by flying masonry or metal fragments. In all these cases a lumbar puncture was performed shortly after they were admitted, and in some of them repeated punctures were carried out.

Lumbar Puncture Pressure

The cases have been divided into three groups, of low, normal, and high pressure, the normal pressure being taken as 90 to 180 mm. of water. In 42 the pressure was within normal limits, in 28 it was above 180 mm., and in 15 it was below 90 mm. An attempt has been made to correlate the pressure with features of the clinical state.

TABLE I

State of Consciousness	Lumbar Puncture Pressure		
	0-90 mm.	90-180 mm.	Over 180 mm.
Full consciousness	11	27	9
Drowsy	2	8	11
Restless stupor	1	5	6
Coma	1	2	2
Total	15	42	28

These findings were recorded at the time of the first lumbar puncture; in many cases this was done within twenty-four to forty-eight hours of injury, but in others, owing to delay in admission to a head injury centre, it was not carried out for seven to ten days. It will be seen from Table I that the pressure of the cerebrospinal fluid in the lumbar sac bears little relation to the patient's state of consciousness: deep coma can be present with a normal or low pressure as well as with a high one. It is, however, true that drowsiness is a frequent symptom in patients with a high pressure, though it is not confined to them.

TABLE II

Condition	Lumbar Puncture Pressure		
	0-90 mm.	90-180 mm.	Over 180 mm.
No headache	11	24	1
Moderate headache	2	8	10
Severe headache	0	3	9
Stupor or coma	2	7	8

In the acute stages of a head injury the lumbar puncture pressure bears a closer relation to the degree of headache present than to the state of consciousness. It will be seen from Table II that only one patient with a high pressure

was free of pain. He was a soldier admitted six days after a motor-cycle accident from which he had been unconscious for five days, and though his lumbar puncture pressure was 300 mm. he showed no symptoms. In all the other patients with high pressure who were conscious headache was complained of, and in 9 of them it was severe and not necessarily accompanied by blood in the C.S.F. In the low-pressure group bad headache was not a feature, but 3 of the patients with normal pressures had severe pain.

The same relation does not appear to hold in patients with late post-traumatic headache, in whom the lumbar puncture pressure is usually within normal limits but occasionally low.

Pulse Rate

As a slow pulse rate may be found soon after a closed head injury with any degree of C.S.F. pressure it cannot be taken as a reliable index of a raised intracranial pressure. Further, the pulse rate may remain slow when the pressure is rapidly reduced. The presence of a slow pulse rate with a normal C.S.F. pressure in head injuries has been remarked on by Denny-Brown (1941), and has been ascribed by him to medullary contusion. This explanation would be compatible with the persistence of a slow rate in spite of rapid reduction of intracranial pressure.

Reduction of Increased Pressure

Patients with a raised C.S.F. pressure who have had only small quantities of blood in the fluid have been treated by dehydration by means of hypertonic enemata of 6 oz. of 50% magnesium sulphate administered twice daily. In most cases this method has succeeded in reducing the pressure and relieving symptoms. In a few patients severe headache has continued and the pressure has remained high in spite of this treatment, and to them 40 c.cm. of five-times-concentrated serum has been given intravenously. This treatment has usually resulted in a fall of pressure and often a dramatic relief of headache. An account of this group of cases is in preparation.

As a rule, in uncomplicated cases the clinical condition improves as the C.S.F. pressure falls, but in one case of closed injury in which the clinical condition remained stationary, though the C.S.F. pressure fell, an extradural haematoma was found at necropsy.

This patient was a soldier, aged 20, who was admitted five days after an injury of which no details were available. He had been admitted to another hospital, where he was found to be in a semi-comatose state with right-sided spasticity, but no pupillary or reflex changes. When seen by me he was in a restless stupor, and had a small sutured scalp wound in the left frontal region; there was slight weakness of the right side of

the face and right arm and leg, all the tendon jerks and the abdominal reflexes were absent, the plantars were flexor, and the fundi and pupils were normal. Radiographs of the skull showed no fracture, and lumbar puncture pressure was 260 mm., the fluid containing 3 cells and 50 mg. of protein per 100 c.cm. As his condition remained stationary a left parietal trephine hole was made, but no haematoma was found. The patient's clinical condition remained much the same as on admission, but the lumbar puncture pressure thirteen days after the injury was 70 mm. and twenty-one days after was 10 mm., the fluid still being normal. He died on the twenty-third day, and at the post-mortem examination a large extradural haematoma containing solid blood clot was found low down in the left temporal region; this had arisen from a torn anterior branch of the middle meningeal artery.

Similarly, in penetrating injuries a space-occupying lesion needing operation may be present though the C.S.F. pressure is falling, as in the following case.

A soldier with a penetrating wound of the left parietal region was admitted in coma with a right hemiparesis on the day on which he was wounded by a bomb fragment. The small external wound had been sutured before admission. His lumbar puncture pressure was 310 mm. and the fluid was deeply blood-stained. In the course of the next twelve days there was gradual improvement and he passed into a restless stupor, the lumbar puncture pressure gradually falling to 140 mm. On the twelfth day the parietal lobe was explored and an intracerebral haematoma was evacuated from it. This was followed by rapid improvement in his condition.

These cases emphasize that in spite of a progressively falling C.S.F. pressure there may still be present a compressive lesion which needs operation, and this is especially likely if the clinical condition does not improve fairly rapidly as the pressure falls.

Blood in the C.S.F.

Blood in moderate quantity may be present after what appear to be comparatively slight injuries which are followed by only a few seconds' post-traumatic amnesia or even no loss of consciousness (cf. McKissock and Browncombe, 1941). The presence of blood in any considerable quantity is accompanied by symptoms, especially headache, neck rigidity, and a positive Kernig sign; but Ritchie Russell's (1932) suggestion that a patient with over 100,000 red cells per c.mm. in the C.S.F. is stuporous or comatose has been found to be not always true.

A man aged 46 had fallen off a ladder on the day previous to admission, striking the back of his head on the ground; he had been unconscious for about three hours. When seen thirty hours after the accident he was drowsy but conscious and co-operative, and there was marked neck rigidity. Lumbar puncture gave a pressure of 270 mm., and the C.S.F. resembled pure blood, except that there was no tendency to clot. Cell counts showed over four million red blood cells per c.mm. and a protein content of 2 grammes %. On the following day, when the count was still over 100,000 red cells per c.mm., the patient was conscious but drowsy.

It is difficult to account for the remarkably high red cell count in this case unless there was gravitation of blood to the lumbar theca.

It is probable that the state of consciousness is not related directly to the quantity of blood in the C.S.F.: it depends rather on the site of origin of that blood. If it comes from cortical lacerations it is likely that there is extensive cerebral damage which will be accompanied by coma or stupor; if it comes from an injured venous sinus there may be profuse bleeding with little cerebral damage, and in these cases unconsciousness may not be present. This latter type of injury probably occurred in the above case, as there was never any further evidence of cerebral damage after the first loss of consciousness, and there was a long crack in the occipital bone.

In cases in which there is blood in the C.S.F. it is important to culture the fluid and to do a differential white cell count on it, as it is possible to ascribe to subarachnoid bleeding the fever and meningeal signs which are usually present, when in reality there is an infective meningitis as well as a chemical one from the presence of blood. This is illustrated by the following case.

This patient, a soldier, was admitted to hospital four days after a motor-cycle accident in France; details of his condition in the first four days were lacking. On admission he was drowsy, had a severe headache, presented meningeal signs, and had a left lower facial weakness. The C.S.F. was under a pressure of 240 mm. and was heavily blood-stained; haemoglobin amounted to 16%, and the supernatant fluid was yellow. During the next three days he became more deeply unconscious, and as he was thought to be bleeding a right subtemporal exploration was performed and a burr-hole made in the left subtemporal region, but no haematoma was found. At post-mortem examination two days later there was seen to be a fracture of the anterior fossa with a purulent meningitis spreading from the posterior wall of the frontal sinus, which was involved in the fracture.

If a culture and a differential white cell count had been made on this man's fluid it is probable that the purulent meningitis would have been recognized; as it was, the meningeal signs were ascribed to subarachnoid bleeding.

Disappearance of Blood from the C.S.F.

Red blood cells usually disappear from the fluid in four to five days; even in the case with over four million cells in the fluid no red cells were found on the fifth day. Occasionally they may persist for considerably longer periods after a closed injury, and it may be assumed that in these cases subarachnoid bleeding has continued for some days. For example, a soldier was admitted eight days after a motor accident in a restless confused state; the C.S.F. contained 100,000 red cells and was under a pressure of 310 mm. It was not until fourteen days after the injury that this man's fluid became free of red cells.

As the red cells disappear it is common for an excess of lymphocytes to persist in the C.S.F., 10 to 20 cells per c.mm. being a common finding. This increase of lymphocytes may last for three to four weeks after severe bleeding: it is usually found even when the yellow coloration of the fluid has disappeared. The presence of more than 2 or 3 polymorphs per c.mm. is unusual after a closed injury unless there is infection.

Protein Content of C.S.F.

The protein content of the C.S.F. shortly after an injury seems to depend on the amount of blood the fluid contains, and it usually falls as the blood disappears, but in the majority of cases in which there has been much bleeding the fall in the protein content is slower than the disappearance of the red cells. Occasionally there is a small rise of 20 to 40 mg. of protein per 100 c.cm. as the red cell count is falling. It seems possible that this is due to corpuscular protein set free by haemolysis, as in the ordinary protein estimation the amount present in the corpuscles is not included, because they are centrifuged off before doing the estimation.

In a few cases the C.S.F. protein remained higher than normal for several weeks after an injury. This does not seem to be related to the severity of the injury, as we have seen 100 to 120 mg. of protein per 100 c.cm. three to four weeks after comparatively minor injuries which were followed by only half an hour to one hour of post-traumatic amnesia. The significance of this continued raised protein content of the C.S.F. is at present undetermined, as the cases do not differ clinically from those in which the protein content has fallen fairly rapidly to normal.

Summary

The pressure and constitution of the C.S.F. have been studied in relation to the clinical condition in 85 cases of recent closed head injury.

The C.S.F. pressure bears little relation to the state of consciousness, but in conscious patients a raised pressure is usually accompanied by headache. The C.S.F. pressure may fall steadily even when a space-occupying lesion is present.

The degree of consciousness is not related directly to the amount of blood present in the C.S.F.; it depends rather on the site of origin of the blood.

The importance of a differential white cell count and a culture on a blood-stained C.S.F. is emphasized. If these are not done the presence of subarachnoid bleeding may mask an infective meningitis.

A lymphocytosis in the C.S.F. may be present for three to four weeks after a severe head injury.

I wish to thank Mr. Harvey Jackson for permission to publish this report, and Dr. Gordon Holmes and Mr. E. B. C. Hughes for their help in its preparation.

AND

B. SEMEONOFF, M.A., B.Ed., Ph.D.

Lecturer in Psychology, University of Edinburgh

Night-blindness has been defined as a disturbance of light perception resulting in a difficulty and occasionally an inability to adapt the faculty of vision to very faint illumination (Jeghers, 1937). Figures as to its incidence in the average population under peacetime conditions are not available. Minor degrees of it are fairly common (Maitra and Harris, 1937; Jeans and Zentmire, 1934, 1936; Schuck and Miller, 1938). It is said to be commoner in the undernourished poorer classes than in the well-fed well-to-do classes (Jeghers). During the war of 1914-18 numerous cases of night-blindness were reported in the armies of the various belligerent countries:

French Army: Bourdier (1916), Truc (1916), Bussy (1916-17), Frenkel (1916-17), Aubaret (1917), Landolt (1917). Belgian Army: Weekers (1916), Danis (1918). Rumanian Army: Savo Goiu (1922). Serbian Army: Néchitch (1918). British Army: Smith (1921), Derby (1921). American Army: De Schweinitz (1921). German Army: Augstein (1915), Best (1915), Braunschweig (1915), Feilchenfeld (1915), Paul (1915), Wessely (1915), Wietfeldt (1915), Zade (1915), Birch-Hirschfeld (1916), Elschnig (1916), Gelenczér (1916), Junius (1916), Löhlein (1916), Rauch (1916), Uthoff (1916), Wolffberg (1916), Hübener (1917), Koepe (1917), Wohlfarth (1917), Hillemanns (1918), Hölcher (1918), Meyer (1918), Sattler (1918), Schieck (1918), Wiese (1919), Jess (1921).

Towards the end of that war cases of night-blindness were seen in increasing numbers in the German Army, and

the problem is again presenting itself there (Fillat, 1940; Hofe and Glees, 1940). Its significance for both the combatant and the non-combatant arms of the Services is obvious. It impairs the efficiency of the soldier: sufferer from this malady are unfit for night guards, night driving and night fighting. In the darkness they are likely to inflict serious injury on themselves or to damage Army property.

Apart from congenital and hereditary night-blindness various views on the aetiology of this disorder have been put forward. It has been attributed to: (1) diseases of the eye (advanced myopia, choroidoretinitis, retinal detachment, optic neuritis, glaucoma, etc.); (2) overexposure to strong light and glare; (3) defective nutrition; (4) toxæmia (diseases of the liver, alcoholism); and (5) great fatigue. The most commonly accepted and, indeed, widely advertised view is that it is due to vitamin A deficiency (Jeghers, 1937; Sweet and K'ang, Frandsen, 1935). This view is regarded as so well established that dark-adaptation tests have been used as a criterion and a quantitative indicator of vitamin A deficiency. Many authors state that patients with night-blindness are often found to be nervous, irritable, and depressed (Duke-Elder, 1932; Elschnig, 1916; Park, 1935; Paul, 1915; Weekers, 1916; etc.). A few writers believe that every night-blind patient is a malingerer (Derby, 1921; Feilchenfeld, 1915; Smith, 1921), a view which has been emphatically repudiated by others (Fillat, 1940). Most authors have recognized and separated a group of cases labelled as nervous or hysterical night-blindness. The neurotic implications of night-blindness have been discussed by Culpin (1940), but so far as is known to us no attempt at a systematic study of the personalities concerned has as yet been undertaken. Everyday experience shows that anxious individuals object more than others to going out in the black-out. Coming out into the street, they cling like frightened children to others and ask for their support. These considerations and the idea that anxiety may be related in some way to dark adaptation prompted us to undertake the following study.

Material: Method of Examination

Biographical studies were made of 52 soldiers complaining of night-blindness who either were sent to us without selection by the eye department or were referred direct to us because of psychological disorders. Their ages at the time of examination were from 19 to 50: 39 of them were under 30 (9 had suffered from night-blindness since childhood, 16 for several years; 13 noted difficulty in seeing in the dark for the first time when the black-out started, and 14 in the course of the war). Four were Regulars, 5 Territorials, 12 volunteers, and 31 conscripts; 43 were privates, 8 N.C.O.s, and 1 an officer. The patients, so far as was possible, were examined ophthalmologically by Major Scott, eye specialist at a military hospital, and were tested for their dark adaptation by Dr. Semeonoff of the psychological department, University of Edinburgh.

Findings

Symptomatology.—All the patients examined suffered from severe night-blindness and stated that they were unable to find their way about in the dark without help from others; they often gave a dramatic description of how, with their arms stretched out in front of them, they groped their way in the dark or clung to their wives, mothers, or comrades. Several of them, unable to see in the dark, had met with serious accidents or had damaged Army or Air Force property—e.g., vehicles.

In association with their night-blindness they often complained of other eye symptoms, such as photophobia, blurring of sight, black spots or floating blobs in front of the eyes, aching or beating sensation in the eyeballs, quivering

of the eyes, etc. Previous spells of complete blindness were reported by 4. Headaches described as shooting or stabbing were complained of by 20, and fits of giddiness, dizziness, or fainting fits by 11; 12 reported symptoms suggestive of effort syndrome, and 10 suffered from rheumatism. Most of the men ate the ordinary Army food and therefore had plenty of vitamins in their diet. Dyspeptics numbered 9, and only in these could the possibility of a reduced vitamin A intake be admitted.

Ophthalmic Examination

At the eye department of a military hospital 42 cases were examined. For purposes of analysis these cases have been divided into five groups, and the results may be summarized as follows:

Group I (13 Cases).—In all of these cases the ocular findings were completely negative, apart from the fact that two of the men exhibited "tubular" fields of vision (although they had no difficulty in orientating themselves in daylight) of the type which one meets in "hysterical" subjects. The fundi were normal in all of these cases. In none was there any ocular cause for the symptom of night-blindness.

GROUP I.—Summary of Clinical Findings

Case	Unaided Vision	Corrected Vision	Refraction	Fundi	Peripheral Fields of Vision
W. C.	R. 6/6 L. 6/6	—	No appreciable error	Normal	Normal
R. W. M.	Only admits R. 6/18 L. 6/24	—	No error	"	Small "tubular" fields
G. A.	Only admits R. 6/18 L. 6/18	—	"	"	Normal
A. M.	R. 6/6— L. 6/6—	—	"	"	"
Sgt. B	R. 6/6— L. 6/6—	—	"	"	"
J. E.	R. 6/6— L. 6/6—	—	"	"	"
J. T.	R. 6/6— L. 6/6—	—	"	"	"
S. M.	R. 6/6— L. 6/6—	—	"	"	"
J. S.	R. 6/6— L. 6/6—	—	"	"	"
H. C. V.	R. 6/6— L. 6/6—	—	"	"	"
B. K.	R. 6/6— L. 6/6—	—	"	"	"
B.	R. 6/6— L. 6/6—	—	"	"	"
N.	Only admits R. 6/36 L. 6/60	—	"	"	Gross contraction. Only admitted small "tubular" fields

Group II (6 Cases).—These men were "one-eyed" for all practical purposes. In two cases one eye had been removed in earlier life, while in the other four the vision of one eye was grossly defective as the result of trauma, inflammation, or amblyopia ex anopsia. In all six cases the good eye was normal, and showed no ocular cause for the night-blindness.

GROUP II.—Summary of Clinical Findings

Case	Unaided Vision	Remarks	Refraction	Fundi	Peripheral Fields of Vision
A. V.	R. <6/60 L. 6/9—	Corneal scarring right eye	No error left eye	Normal left eye	Normal left eye
Be.	R. "P.L." L. 6/6—	Detachment of retina right eye	"	"	"
H. T.	R. Nil L. 6/9+	Right eye enucleated	Very little error	"	"
D. L.	R. "P.L." L. 6/6—	Old penetrating injury, right eye	No error left eye	"	"
Ba.	R. 6/9 L. Nil	Left eye enucleated	Practically no error right eye	Normal right eye	Normal right eye
M.	R. 6/6 L. <6/60	Left eye amblyopic ex anopsia	No error right eye	Normal	"

Group III (11 Cases).—These cases all showed slight errors of refraction, but all had good vision with glasses, and fair vision

without glasses. The fundi were normal in ten of the cases; the remaining one showed a small area of infective choroiditis in one eye. The peripheral fields of vision were normal in all except one patient, who admitted to possessing only a small tubular field in both eyes. In no case was there any ocular cause for night-blindness.

GROUP III.—Summary of Clinical Findings

Case	Unaided Vision	Corrected Vision	Refraction (Axis of Cylinder omitted in Each Case)	Fundi	Peripheral Fields of Vision
H. D.	Only admits R. <6/60 L. <6/60	Only admits R. <6/60 L. <6/60	R. +1.75 L. +1.75	Normal	Only admits small "tubular" fields
T. C.	R. 6/18 L. 6/36	R. 6/6— L. 6/9	Moderate hypermetropia	"	Normal
R. W.	R. 6/9— L. 6/9	R. 6/9— L. 6/9	Slight error; small congenital lens opacity right eye	"	"
W. S.	R. 6/18 L. 6/36	R. 6/9 L. 6/12	R. +2.0 L. +1.5/+2.75	"	"
A. Mc.	R. 6/24 L. 6/24	R. 6/9 L. 6/18—	Moderate hypermetropia	"	"
E. S.	R. 6/60 L. <6/60	R. 6/6 L. 6/9—	R. -1.0/-1.25 L. -2.75/-1.5	"	"
W. M.	R. 6/18 L. <6/60	R. 6/12+ L. 6/24+	Very little error	Choroiditis, left eye	Normal right eye
D.	R. 6/18 L. 6/12	R. 6/9 L. 6/9	Low myopic astigmatism	Normal	Normal
T.	Only admits R. 6/18 L. 6/18	Only admits R. 6/12 L. 6/12	Low degree of astigmatism	"	"
H. C.	R. 6/5 L. <6/60	R. 6/5 L. <6/60	R. +3.0 L. high myopia (amblyopic)	Normal right eye	Normal right eye
F. C.	R. 6/12— L. 6/18+	R. 6/9 L. 6/12+	Moderate astigmatism	Normal	Normal

Group IV (11 Cases).—All of these cases showed moderately high errors of refraction. In five the vision was good when corrected with glasses, which were being worn at the time of examination. Three men had marked amblyopia in one eye, the good eye being normal apart from the error of refraction. Two men had defective vision for which there was no ocular cause, and one of these had typical "hysterical" fields of vision. In ten of the cases the fundi of both eyes were seen to be normal; in one case, which showed a complicated cataract in one eye, the fundus in this eye could not be seen, but the fundus of the other eye was observed to be normal. One of the men in this group had considerable corneal scarring in both eyes, but with vision equal to 6/18 partly and 6/24; this was the only case which showed any ocular defect that one could say might cause a certain amount of difficulty in seeing in dim light.

GROUP IV.—Summary of Clinical Findings

Case	Unaided Vision	Corrected Vision	Refraction (Axis of Cylinder omitted in Each Case)	Fundi	Peripheral Fields of Vision
S. B.	No record	No record	Irregular astigmatism	Normal	Normal
J. F.	R. 6/18— L. 6/24	R. 6/18— L. 6/24	Irregular astigmatism (corneal scarring)	"	"
W. C.	R. "P.L." L. 4/60	Only admits L. 4/60	L. +1.5/+4.0 (cataract right eye)	Normal left eye	Normal left eye
W. W.	R. 6/36 L. <6/60	R. 6/12— L. 6/18	R. +0.5/-3.5 L. -2.75	Normal	Normal
H.	R. <6/60 L. <6/60	R. <6/60 L. 6/12—	R. +6.0/+3.0 L. +6.0/+2.0	"	Normal left eye (right eye amblyopic)
A.	R. <6/60 L. <6/60	R. 6/9— L. 6/9—	R. -2.5/-0.75 L. -2.0/+0.75	"	Normal
R.	R. <6/60 L. <6/60	Only admits R. 6/36 L. 6/24	R. -3.25/-4.0 L. -2.0/-4.0	"	"

K.	R. 6/36 L. 6/60	R. 6/6 L. 6/18	Moderately high astigmatism	"	Normal
P. P.	R. 6/36 L. 6/6—	R. 6/36 L. 6/6—	L. +6.0/+2.0	"	Normal left eye (right eye amblyopic)
E.	R. <6/60 L. <6/60	Only admits R. 6/36 L. 6/60	R. -1.75/-1.25 L. -1.5/-0.75	"	Typical "hysterical" fields

Group V (1 Case).—This man showed degenerative choroido-retinitis involving the peripheral parts of both fundi. The case was diagnosed as one of "retinitis pigmentosa," although in some respects the appearances were atypical. The night-blindness was, however, undoubtedly due to organic disease of the choroid and retina in this case.

GROUP V.—Summary of Clinical Findings

Case	Unaided Vision	Corrected Vision	Refraction	Fundi	Peripheral Fields of Vision
W.S.	R. 6/6— L. 6/60	—	No error.	Degenerative choroido-retinitis both eyes	"Ring scotoma" right eye Marked contraction left eye

Summary of Findings

1. In 41 of the 42 cases examined there was no ocular cause for the night-blindness. One man had corneal scarring that might perhaps cause a certain amount of difficulty in seeing in dim light, but only one case showed disease of the eye sufficient to cause true "night-blindness."

2. In no case was there any suggestion of xerosis of the conjunctiva or of the corneal epithelium.

The further significance of these findings will be discussed later in this paper.

Dark-adaptation Examination

Of the 52 cases studied 40 were tested for dark adaptation in the George Combe Psychological Laboratory, University of Edinburgh. The instrument used was the Nagel adaptometer (Nagel, 1907), and the method of testing as described elsewhere (Semeonoff, 1941). Since it was felt that the results obtained with this instrument might be influenced by general intelligence, the men were tested with Group A of the Herring revision of the Binet-Simon test. In two cases the eye condition made it impossible to apply this test, although these men were able to take the test of dark adaptation.

By way of control a group of 33 soldiers, chosen at random, was tested for dark adaptation and intelligence in the same way as the night-blind group. Certain features of the two groups are compared in the following table.

Comparison of Night-blind and Control Groups

	Night-blind Group (40 Cases)	Control Group (33 Cases)
Age:		
Highest	50	44
Median	27	25
Lowest	19	18
Intelligence (raw scores):		
Highest	36	38
Median	25	30
Lowest	14	21
No. with post-elementary education (any type)	6	14

It will be seen that the groups are not quite identical in respect of age, education, or intelligence, and, moreover, a high proportion of the control group had various visual abnormalities. Three, indeed, mentioned that they experienced considerable difficulty in night vision. The control group must be regarded as a fairly random sample of Army personnel rather than as a group of "normals."

The testing technique and treatment of results were briefly as follows. A period of forty minutes' dark adaptation followed ten minutes' preliminary light adaptation to a white surface of about 40 foot-candles illumination. During dark adaptation, readings of threshold intensity were taken at intervals, usually of five minutes. Sensitivity was measured in terms of logarithms of reciprocals of successive threshold values, zero corresponding to the maximum intensity of the adaptometer. Curves based on these sensitivity values were drawn, and smoothed in such a way as to eliminate or at least minimize the effects of accidental or other irregularities. Different measures of amount and rate

of dark adaptation were derived from these curves, and it eventually appeared that, although these were almost interchangeable, the most reliable single measure was the maximum sensitivity attained during the test period, as shown by the course of the smoothed curve.

It must be noted that actual sensitivity to light under conditions of low illumination was being tested, and not ability to discriminate detail under these conditions. The latter, as Ferree and Rand (1938) point out, is by no means the same thing as the former, and is probably of greater significance in the ability to "see in the dark." Nevertheless, pure sensitivity to light may be assumed to be more closely associated with the actual physico-chemical processes which take place in the retina, and which would therefore be more directly affected by nutritional causes, assuming that these could be operative.

The distribution of dark-adaptation measures for the two groups is given in Fig. 1. Average figures are: night-blind cases, 2.6; control group, 3.6.

Fig. 1.—Distribution of dark-adaptation measures. A+ = 4.0 and over—high normal. A = 3.5–3.9—low normal. B = 2.5–3.4—subnormal. C = 1.5–2.4—defective. D = below 1.5—grossly defective.

It is necessary also to consider the possible effect of extraneous influences, such as those of age and intelligence, though the small numbers in each group reduce the reliability of any conclusions. Ferree *et al.* (1935, 1938) have shown that power of dark adaptation decreases with age, though the effect is more notable for discrimination of detail than for actual sensitivity to light. In the present control group a high negative correlation between age and sensitivity was found (-0.78 ± 0.049), though this was strongly influenced by two cases of men over 40 who were the only "C" and "D" patients in this group. In the night-blind group, on the contrary, a non-significant positive correlation was found ($+0.27 \pm 0.099$). As regards intelligence, positive correlations with dark adaptation were found for both groups (controls, $+0.46 \pm 0.094$; night-blinds, $+0.31 \pm 0.099$). Since intercorrelations of sub-tests for the two groups suggested that the Herring revision presented a virtually different situation for neurotic and normal subjects, it was felt that general educational level might prove a truer basis for comparison, particularly since the proportion of control cases with any sort of post-elementary education was much higher than in the night-blind group. The average dark-adaptation measure of the six night-blind men of this type was identical with that of the whole group (2.6); in the control group, which included fourteen such cases, the average was slightly higher (3.9, as against 3.6 for the whole control group).

The general conclusion seems to be that among normal persons higher intelligence and educational level and lower age are associated with superior dark adaptation, while for "night-blind" cases such influences are wholly or in part obscured by other factors.

'Psychiatric Examination

On psychiatric examination the soldiers studied were found to be psychologically abnormal far beyond the range of individual differences in the average population. In fact most of them, quite apart from their night-blindness, were unfit for military service because of their psychological abnormalities and disorders.

Nature and Degree of Psychological Disorder

Using a modified Culpin scale, the patients were divided into four grades according to the degree of their psychological disorder:

0. No obvious psychological disorder.
1. Minor psychological abnormalities not sufficient to interfere with an ordinary mode of life.
2. Psychological disorders interfering with activities but not incapacitating.
3. Psychological disorders temporarily or permanently incapacitating.

The grading was exclusively based on psychiatric findings, and the night-blindness itself was not taken into account. Grade 0 was absent in the series: 9 patients were classified as Grade 1, 12 as Grade 2, and 31 as Grade 3.

While fully aware of the very limited value of psychiatric labels, we nevertheless tried to classify the patients according to their psychiatric diagnoses. In doing this Grade 1 was left out of consideration for obvious reasons. Of the 43 patients classified as Grades 2 and 3, 14 suffered from acute and 13 from chronic anxiety states—i.e., more than half of the total of 52 were anxiety states—8 were cases of conversion hysteria, 4 were cases of depression, and 3 were psychopathic personalities of the schizoid or of the over-aggressive type. One patient was unclassifiable. These are some illustrative examples:

Grade 1.—A soldier aged 34, unaggressive and averse to mischief as a child, has always been very shy and prone to blushing. Until he was 16 he stuttered very badly, and he still has a slight impediment of speech.

Grade 2: Chronic Anxiety State.—A soldier aged 28 complains of sleeplessness. He does not feel sure of himself and has always worried unduly about his work and his duties. He believes that other people stare at him and pass remarks about him. He has always been unaggressive, over-compliant, timid, afraid of darkness and of being hurt, and has been unduly concerned about his eyesight. Until the age of 14 he was a stutterer; he is still a nail-biter and prone to bed-wetting. He is unduly attached to his mother, and if she is taken ill he feels ill himself.

Grade 3: Acute Anxiety State.—An extremely efficient R.S.M. aged 44 had an acute nervous breakdown after a period of over-work, and one day, marching at the head of a column, he collapsed. Afterwards he felt very anxious, for no reason known to him. He could not travel unless there was a corridor in the train by which to get out. He felt unable to go to the pictures unless he was seated near the exit. Every time he had a hair-cut he wanted to get out of the chair. He felt better when in company but, on the other hand, he dreaded meeting people. He also suffered from palpitation, dizzy spells, breathlessness, sleeplessness, and a feeling of exhaustion.

Conversion Hysteria.—A soldier aged 24 developed a peculiar disturbance of gait after an accident. He felt that his left leg was giving way, and he constantly stumbled. While he was in hospital for an examination of this disorder, which was found to be hysterical in origin, he suddenly felt unable to rise when seated and also lost his voice.

Depression.—A sergeant aged 43, feeling rather tired, went on leave. On return to his unit the tiredness persisted and he became very irritable. He suffered from headache and sleeplessness, was afraid of giving orders and of meeting people, and had difficulty in making decisions. He carried on his duties until, three months afterwards, he broke down completely, became very depressed, did not care if he were killed in air raids, and "howled like a kid" for no definite reason. He had no confidence in himself, felt that he was no use for the Army, and wanted to get out of it.

Personality Types

Correlation and mathematical evaluation of childhood characteristics carried out on these patients, according to

a method previously described, enabled us to delineate certain personality types.

The majority of the men were of an over-dependent type; a minority were ostentatiously independent. At the one end of the scale are individuals who have kept up a dependent childlike attitude even in adult life; they are perpetual children. Towards the centre of the scale there are men with strong feminine tendencies, more or less successfully concealed; they present merely a façade of masculinity. At the other extreme are men who have a compulsive and clearly reactive and over-compensatory need to demonstrate their masculinity to everyone and anyone; they succeed in being regarded as he-men.

1. OVER-DEPENDENT TYPE

Of the total of 52 soldiers 27 were of the over-dependent type. The majority were either delicate in health or had been definitely ailing as children. A fair number lost their father in early life and grew up in purely female surroundings. In others admiration for their father, whose physique or mental outlook represented their much-envied ideal, was mingled with a dread of his sternness or violence. Being delicate in health, they were often doted upon by their over-anxious and over-solicitous mothers, to whom many of them were grossly over-attached. Undue dependence on their mothers often extended into adolescence or even adult life. Many of them are still nicknamed "Mummy's pet" or "Mummy's darling" in the family circle. Some, on the other hand, felt or actually were unwanted, were neglected or ill-treated, and had in consequence a lifelong craving for love and affection. Any display of affection to one of their siblings roused undue resentment and jealousy in them. Most of them stated that they were unfit for games, and, at any rate, afraid of getting hurt; they preferred indoor activities to outdoor rough-and-tumble. Some were definitely lazy and liked best lying about or hanging about in the house. Some were helpless as children, constantly falling and getting cuts and stitches. Many of them took a great delight in girlish activities, such as washing dishes, scrubbing, and dusting (sometimes even in adult life). "Mother often said I should have been a girl," several of the patients said. They had little inclination to associate with other children at all and, if they did, they preferred girls' company. "Boys are too rough for me," they often stated. Certainly not entirely accounted for by their physical ill-health, most of them lacked aggressiveness. If they were attacked they burst into tears and ran home for their mother's or their strong brother's protection. Extreme cases endured even tormenting by other children without any attempt at retaliation or protest. One of the patients allowed himself to be rolled in the mud by other children and did not even take the trouble to remove the dirt. Smarting from such humiliations, they indulged in fantasies of strength and power, often modelled upon their strong fathers and brothers, but their actual efforts were weak and often pathetic. Most of them were timid, shy, and self-conscious. They were subject to numerous morbid fears and other nervous symptoms.

Six of the patients maintained their childhood characteristics practically unchanged in adult life. They were unhappy creatures, a burden to those around them, unemployable and useless members of the community. Seven others were poor workers, clumsy and unintelligent, and handicapped by their morbid fears. They were shiftless in their occupations, were frequently dismissed, and had long spells of unemployment. Eleven did moderately well, and four even excelled in their occupations, but their ostentatious zeal, zest, and over-conscientiousness were clearly anxiety-motivated, and gave way to complete passivity once they came up against serious and apparently insuperable difficulties. One of these, an N.C.O., had distinguished himself in numerous examinations and in the execution of his duties, but he broke down during the war of 1914-18 after severe shelling, and again in this war when his unit was about to be sent to France. Two men, after a completely passive attitude in childhood, went through a phase of great audacity and over-aggressiveness in adolescence and adult life, only to fall back again into a state of complete passivity when eventually they broke down. Over two-thirds of the men in this group are of a retiring disposition in their social contacts:

they are quiet, unassuming, unaggressive, tender-hearted people who prefer long walks alone in the country to being at parties or in crowds, where, without justification, they feel that everybody is looking at them or passing remarks about them. Even if they appear well adjusted, they are timid anxious individuals, unduly dependent on and swayed by the opinion of others. Whatever they do is carefully weighed up beforehand, because of their preoccupation with potential adverse consequences. Some are shy in front of women or are even terrified of contact with them. Others state quite frankly that they feel more at home in their company. "Girls understand me better than boys," several said. If they marry they choose a sisterly or maternal type of woman who looks after them. They are meek and docile husbands, and if their wives are domineering, or even if they are unfaithful, they submit without protest. As might be expected, with very few exceptions they are poor soldiers. They are isolated in their units and often the butt of their comrades.

2. OSTENTATIOUSLY INDEPENDENT TYPE

This group comprises 12 patients, basically similar in structure to, though superficially just the reverse of, the first group. They adopt an active, energetic, masculine attitude towards life, but the ostentatious nature of their conduct and behaviour bears the stamp of its reactive over-compensatory origin. Vaguely aware of their inherent passive feminine trends, they have to show the world how tough they are, for fear of being found out.

They were usually robust as children, mixed easily and liked parties, whose "life and soul" they were anxious to be. They were good organizers, always ready to assume leadership. They liked to be in the forefront of everything, were involved in any mischief that was going, and were often the leaders of the local gang. They were stubborn and cheeky at home, and argumentative and quarrelsome with other children if these did not fall in with their views and arrangements. Like the members of the first group they indulged in grandiose fantasies, but in contrast they put them into action. They were fond of taking risks, excelled in sports and games, and, in general, "liked to show off brute strength," as one of the patients put it. They liked fighting for the fun of it, and prided themselves on having acquired such nicknames as "Tiger" or "Champ." Many of them, however, realized that this was not their real nature: behind a façade of self-assertiveness they were shy and diffident. They blushed easily, and joking insinuations implying their possession of girlish characteristics upset them unduly. A few fainted easily if it came to actual fighting, and almost all of them shamefacedly admitted they had always been subject to numerous morbid fears.

Half of them, in whom self-driving ambition and wish to show off prevailed, made a success in life before their breakdown. One of them, anxious to demonstrate his heroism, joined "the toughest tramp-ship company afloat." The others were either lazy good-for-nothing loafers or got into trouble because of their aggressiveness. Strange as it may appear, this group includes the only female member of the series. Grossly over-attached to her mother from early childhood onwards, she "went for" her drunken father on many occasions. Afterwards, in the face of many hardships, she tried to live up to her very high and rigid Spartan ideals. She joined the A.T.S. at the outbreak of war, and became severely depressed after her father's death through enemy action.

Their main characteristics fit these men well for soldiering. A few have distinguished themselves by their bravery; four who were poor soldiers were either inefficient from the start or became involved in disciplinary difficulties.

3. MIXED REACTION TYPES

The remaining 13 patients showed no predominance of their dependent or independent tendencies. They have certain characteristics in common with both preceding groups without falling into either of them. This group includes individuals who, struggling against a constitutional handicap, tried more or less successfully to emulate their strong brothers and fathers; chronically anxious individuals who somehow managed to master their morbid fears; apparently fearless individuals with deep-seated conflicts over aggressiveness; and solitary individuals without manifest social anxiety. Three patients of this group showed only minor personality deviations which approximated very closely to the normal.

(To be concluded. References will be given with Part II)

THROMBOSIS IN ARTERIOSCLEROSIS OF THE EXTREMITIES

BY

E. D. TELFORD, B.Chir., F.R.C.S.

Emeritus Professor of Surgery, University of Manchester

AND

H. T. SIMMONS, M.D., Ch.M., F.R.C.S.

Research Fellow, Manchester Royal Infirmary

(From the Neurovascular Clinic, Manchester Royal Infirmary)

At 25 years of age the arterial tree is seen at its best, and from this time onwards signs of wear and tear begin to appear. The downward course is slow and insidious, and the extent of the changes seems to depend more upon inherited quality of the arterial wall than upon any other single factor. Nature, however, possesses immense reserves, and, in general, the stiffened wall and reduced calibre give rise to no significant symptoms, though they no doubt play a part in the loss of bodily strength and mental alertness in later years.

In those arteriosclerotic patients in whom the embarrassment of the peripheral circulation of the limbs becomes serious the first signs of trouble are usually a persistent coldness of the extremities and an arresting cramp in the calf or foot on exertion (intermittent claudication). The walking distance gradually lessens; colour changes appear, at first rubor and later cyanosis. Finally, severe and continuous rest pain in the dusky digits is ominous of impending gangrene.

There are, however, other cases of arteriosclerosis in which serious consequences descend like a bolt from the blue in patients who have had no previous warning of any defect in their peripheral circulation. These accidents appear to result from a sudden thrombosis, and when one thinks how commonplace is thrombosis of the cerebral or coronary arteries it is not surprising that similar catastrophes should occur in the arteries of the limbs. During the last few years we have studied 19 cases in which sudden thrombosis of arteriosclerotic arteries has occurred, and we have watched the course of these patients over long periods. Of the 19 patients 16 were men and 3 women. The lower limb was affected in 17 cases and the upper in 2. The average age was 53, which indicates that thrombosis of the arteries of the limbs happens at a relatively early age in a patient who, already arteriosclerotic, is still capable of considerable muscular effort.

Symptoms

In most of our cases the attack has developed during a spell of active exertion—e.g., cycling uphill, climbing the gangway of a ship, pulling on a rope—and in one instance the trouble followed immediately on a fall from a lorry.

The first symptom is a sudden pain of crippling severity, usually in the calf. On examination the foot is found to be cold and waxy, and no pulsation can be felt. The acute pain usually abates and the limb then presents the well-known signs of arterial embarrassment; it is cold, shows rubor in the dependent position, and all active movement is sharply limited by the onset of severe cramp in the calf or foot, often within a few yards. Very gradually—it may be several weeks—the condition improves as some collateral circulation slowly comes into play, but recovery is always far from complete; some degree of claudication, cold, and rubor persists. Gangrene is not common, and

when it does occur—it is usually slight and limited to the distal parts of one or more digits. In only one of our patients was amputation of the limb necessary for gross gangrene.

The cardinal feature is therefore the sudden acute onset followed by a severe claudication which, unlike that of progressive arterial disease, tends steadily to improve as some amount of collateral circulation develops. These features are shown in Cases 1 and 2—the one in the upper, the other in the lower, extremity.

Case 1.—A farmer aged 51 was pulling hard on a rope when he was seized with a severe pain in the right forearm and wrist. Within a few minutes, his hand became cold, white, and completely useless. He went to his doctor, who found that the right radial pulse was absent. The pain gradually diminished, but the hand remained useless. When we saw him some months afterwards the right hand and forearm were wasted, cold, and pale; moderate exertion brought on severe cramp. There was no pulse at the wrist or bend of the elbow, but a strong pulse was felt in the upper half of the brachial artery. A right cervico-dorsal ganglionectomy was done, and gave a good result. He went back to his work and was able to do milking and other jobs on his farm. This patient eventually died suddenly from a coronary thrombosis eighteen months later.

Case 2.—A labourer aged 44 was crippled by a sudden pain in the right calf while walking to his work. We saw him in September, 1938, and at that time there was no pulse in or below the popliteal. The foot was cold, showing distinct rubor but no loss of tissue. He was unable to work, and could walk at best less than 400 yards, when he was stopped by severe cramp in the calf. He was seen at frequent intervals, and as he showed no improvement lumbar-cord ganglionectomy was done in April, 1939. This gave a good result. He is still at work, and can walk a mile at a good pace before he feels pain in the calf.

Pathology

The clinical features of all these cases suggest that there has occurred a sudden deposit of clot upon an atheromatous ulcer of the intima, and in one case we were able to obtain the thrombosed popliteal artery. This case was that of a man who at the early age of 33 was seized with a sudden thrombosis of the right popliteal artery. A massive gangrene of the foot developed, and amputation was inevitable. On naked-eye examination the artery showed gross arteriosclerosis; its wall was stiff and thickened, and its lumen over a length of three-quarters of an inch was blocked by a thrombus. Under the microscope it was seen that this was an organized thrombus situated on an ulcerated area of the intima; the media showed hyaline changes such as are found to precede calcification.

Diagnosis

Owing to the pain in the calf on walking these cases are apt to be wrongly diagnosed as "rheumatism," and owing to their onset during muscular exertion they have been taken for instances of ruptured muscle. These mistakes, which may be followed by useless and even harmful treatment, should be avoided if attention be paid to the coldness, pallor, and absence of pulse distal to the thrombosis.

Arteriosclerotic thrombosis is not likely to be mistaken for the acute embolism of cardiac disease. This latter is more acute, it happens usually in a patient already known to have a serious cardiac lesion, and it leads rapidly to massive gangrene because the post-embolic thrombosis is apt to extend over a great length of the artery and its extension blocks the collateral channels.

There should be no difficulty in excluding thrombo-angiitis obliterans, because this disease is found usually in younger men and, although its chronic course may be

rise to a sudden incapacity. Moreover, in thrombo-angiitis obliterans there may be a history of phlebitis migrans, and in the more advanced cases the periarticular fibrosis can readily be felt as a massive deeply seated thickening in the popliteal space.

The actual diagnosis that the lesion is arteriosclerotic can be made only by section of an artery or by radiographic evidence of flecks of calcium in the arterial wall. This latter evidence is, however, available only when the degeneration is advanced.

The diagnosis of arteriosclerosis as the cause of the thrombosis depends upon the summation of a number of observations, no one of which is pathognomonic. Such are family history, age, premature greyness, arcus senilis, hardening and tortuosity of radial and brachial arteries, raised blood pressure, hypertrophy of left ventricle, and increased aortic second sound. Too much stress should not be laid on age or blood pressure. In one of our cases the age of the man was 33, and in another the systolic blood pressure was 120.

Treatment

Beyond the use of sedatives for pain there is little that can usefully be done during the first few days after the acute onset. We could, however, draw attention to what has seemed to us a point of importance in the nursing of the case. It is customary in the treatment of deficient arterial circulation in the lower extremity to send the patient to bed and to keep the limb horizontal or even elevated; some form of heat or warm wrappings are usually employed. We believe this line of treatment to be wrong. The raised position encourages the veins to drain away too rapidly a blood supply which is already gravely limited by the arterial block; an increase in the ischaemia results and the starved extremity may be pushed over the brink of gangrene. The correct handling of such a limb is to keep it dependent and cool. It is remarkable how quickly patients with deficient arterial circulation learn to hang the limb over the edge of the bed in the open.

With the disappearance of pain the patient may be encouraged to get about, and the treatment should be directed to obtaining some degree of vasodilatation. Padutin or similar drugs and hot and cold contrast baths, with postural exercises, may be used with advantage. Treatment by intermittent venous occlusion is well worth a trial, and has seemed to bring about some improvement in several of our patients. Massage, radiant heat, and electric therapy should be avoided; they may be actually harmful.

Should the condition appear to hang fire after a thorough trial of expectant treatment, and if the patient still shows a restricted circulation with a very limited walking distance or the presence of a persistent ulcer, onychia, or other trophic disturbance, we would advise that a lumbar-cord ganglionectomy should be done. In those of our patients on whom we have thought it advisable to do this operation the result has been very gratifying. Case 3 is a typical instance.

Case 3.—A labourer aged 57 was thrown violently from a moving lorry in September, 1933. Immediately after the accident he felt severe pain in the left calf and found that his foot was cold and white. The acute symptoms passed off in a few days, but left him unable to work owing to claudication at 100 yards and a persistent and very painful ulceration of the third toe. When seen four months after the accident he was a tired man who had lost flesh and energy from pain and want of sleep. His blood pressure was 128/80, and the arteries of his legs showed many flecks of calcareous deposit. In the left lower extremity no pulse was felt in the popliteal artery or at any point below. An indolent gangrenous ulcer covered most of the medial surface of the third toe. Lumbar-cord ganglionectomy was done, with the result that pain was at once abolished

and the ulcer was healed within three weeks. He has been seen since on many occasions, and when last examined, seven years after the operation, he was in good general condition, able to do some work and to walk at least 300 yards without trouble.

Prognosis

The prognosis of this form of thrombosis may be described as good with regard to the life of the limb, but as poor with regard to function. Some degree of claudication and restricted use is the rule.

Summary

A condition of sudden thrombosis in the arteries of the extremities is described and treatment is discussed. For the more severe and persistent disabilities section of the sympathetic supply is advocated.

VOLVULUS OF CAECUM, ASSOCIATED WITH PUTRID PUERPERAL ENDOMETRITIS AND GANGRENOUS VULVITIS

BY

ISAAC ROSE, M.B., Ch.B., D.R.C.O.G.

Medical Officer in Charge, St. Helen Municipal General Hospital, Barnsley

The following case should prove of interest to the consultant obstetrician as well as to the general practitioner.

Case Report

A primigravida aged 38 was admitted to St. Helen Hospital at 3 p.m. on November 19, 1940, with "obstetric shock and complete perineal tear." About seventeen hours before admission she had been delivered, with forceps, of a stillborn infant twenty-two inches long. The delivery had been difficult—the head at 10.40 p.m. and the shoulders at 11.20 p.m.

On admission she was extremely ill, restless, dyspnoeic, cyanosed, and toxæmic. Her temperature was 97°, pulse 132, and respirations 32. The heart sounds were rapid, soft, and muffled in character, with systolic bruits over the praecordium. The chest was clear, but there was extreme gaseous distension of the abdomen, with generalized tenderness but no rigidity. Vaginal examination revealed a stinking lochial discharge and a complete perineal tear, the edges being black and gangrenous for half an inch on each side. The infection must have been very virulent to cause gangrene within seventeen hours of delivery.

Owing to her extreme restlessness 1/3 grain of morphine was prescribed. Mixed anti-gas-gangrene serum (40,000 units) was injected intramuscularly and subcutaneously, compresses of 50% aqueous urea solution were applied locally to the perineum, ergometrine was given, and she was nursed in the high Fowler position. I was greatly interested in her pronounced abdominal distension, as within the previous two years I had seen the following three cases, in which this extreme distension was a prominent feature:

Case A.—A multigravida with obstetric shock. Forceps had been applied by her own doctor with the head "floating" and the cervix not fully dilated. A deep left lateral cervical tear was caused, opening up the base of the broad ligament, with rupture of the cervical branch of the uterine artery, producing a huge retroperitoneal haemorrhage extending from the pelvis to the left perinephric region. In this connexion Berkeley, Bonney, and MacLeod (1938a) state: "It is important to remember that haemorrhage under the peritoneum produces even more marked flatus distension of the intestines than that taking place into the abdominal cavity, and if the patient lives long enough this will be a very pronounced sign."

Case B.—A primigravida with a complete perineal tear (after difficult forceps delivery for an occipito-posterior presentation). She had puerperal pyrexia, phagedaena of the perineum, and extreme abdominal distension, which had been

diagnosed as pelvic peritonitis. She was extremely ill and toxæmic, vomited excessively, and looked so much like a case of paralytic ileus that I decompressed her gradually, using Holt's modification of Wangenstein and Paine's technique (Holt, 1936). She was completely deflated within twelve hours, and made an uneventful recovery under the usual routine treatment.

Case C.—This patient had puerperal pelvic peritonitis due to haemolytic streptococcal infection which cleared up after suprapubic drainage under local anaesthesia and sulphonamide therapy. In this respect Berkeley, Bonney, and MacLeod (1938b) state: "Great difficulty is experienced in diagnosing the presence of peritonitis [in the puerperium] and its characteristic signs, since those of rigidity and acute tenderness are frequently absent. The patient usually complains of abdominal pain, though tenderness is not pronounced. On the other hand, distension and the presence of diarrhoea are highly suggestive."

Bearing these three cases in mind, I carefully exposed the cervix with a speculum and found it to be intact. At the same time cervical and vaginal swabs were taken for culture. A tentative diagnosis of post-partum paralytic ileus or of post-partum peritonitis was made. Throughout her stay in hospital the patient did not vomit.

Slow intestinal decompression by the Holt-Wangenstein-Paine method of suction by duodenal tube was instituted, and, while the apparatus appeared to be working satisfactorily, there was not the dramatic deflation that was seen in Case B, although the abdominal distension was not so pronounced as on admission. The duodenal tube was left *in situ* for twenty-four hours. The patient's general condition improved, but her temperature began to rise. A further 40,000 units of anti-gas-gangrene serum was injected, and 1 gramme of sulphanilamide was given four-hourly. She took nutritious drinks and light diet readily.

The patient became very restless in the early hours of November 21, and morphine 1/3 grain was administered. At 10 a.m. she collapsed and was given a hypodermic injection of atropine 1/100 grain, adrenaline 5 minims, and strychnine 1/60 grain, this being repeated four-hourly for six doses. Later in the day 30,000 units of anti-gas-gangrene serum was injected. She was very restless and the abdominal distension had increased. I considered it unwise to give her enemata, as the bowel contents would be returned via the vagina and probably aggravate the local gangrenous condition. At 6 p.m. she was extremely ill, with rapid thready pulse and cold and clammy skin. A pint of human citrated plasma, Group A(II), was given intravenously, followed by a small suprapubic incision and drainage under local anaesthesia. A large quantity of sero-sanguineous fluid escaped, some of which was sent for examination and culture. The tentative diagnosis of peritonitis appeared to be justified. On return from the theatre her general condition was improved, but the abdominal distension was still severe. A further 40,000 units of anti-gas-gangrene serum was given intramuscularly and 20,000 units intravenously. Her general condition became poor again at 9 p.m., and 1½ pints of Group A(II) citrated plasma was given intravenously, followed by glucose saline drip. She improved for a few hours, then gradually became worse in spite of stimulants, prontosil soluble, and calcium gluconate therapy. She died at 11.50 a.m. on November 22.

At necropsy a volvulus of the caecum and about two inches of the ascending colon was found, with a twist of one and a half turns. The caecum was enormously distended, its walls showing patchy areas of haemorrhage, but there was no gangrene. The apex of the volvulus appeared to be the site of a mass of inflamed tuberculous mesenteric glands. There was a gangrenous vulvitis and vaginitis with putrid endometritis. The pelvis was a typical small one, through which an average-sized foetus would be delivered with great difficulty. Culture of the cervical and vaginal swabs gave a growth of haemolytic and non-haemolytic streptococci, staphylococci, and *B. welchii*. Culture of the peritoneal fluid produced a growth of haemolytic and non-haemolytic streptococci, *B. coli*, and *Staph. albus*.

An inquest was held, and the midwife who had supervised the patient ante-natally gave the following facts in her evidence: (i) The patient had vague pains on November 11. (ii) The pains had gone on the 12th. (iii) On the 14th an enema was returned clear. (iv) The membranes ruptured on the 16th—no pains. (v) Pains began again on the 17th, but were weak and

irregular. The bowels had not acted. An enema was returned clear. (vi) The patient fell out of bed on the evening of the 17th and broke an iron fender in her fall. The midwife noticed that the abdomen seemed larger after this accident. On being questioned she stated that the distension was more pronounced below the umbilicus—no bruising was seen on the abdominal wall. The midwife was not aware of the post-mortem findings.

Discussion

The most interesting question is, When did the volvulus occur? Had the injury on the evening of November 17 pre-disposed to this condition? The bowels had not been opened from November 14, when the result of an enema was clear. Clifford White (1914) recorded a case of volvulus of the caecum that was not diagnosed before operation, and asked, "When did the volvulus occur?" Margaret Basden (1934) reported the case of a woman in labour in whom laparotomy (and Caesarean section) was done for a suspected intra-abdominal condition and a volvulus of the caecum was found at operation. J. H. Spence (1937) quoted a case of volvulus shortly after delivery in which too much attention was paid to the associated uterine infection. He stated that "during pregnancy and the puerperium there should not be much delay in performing laparotomy in doubtful cases."

Extreme abdominal distension occurring in the puerperium may be due to (1) pelvic peritonitis; (2) a condition simulating paralytic ileus; (3) retroperitoneal haemorrhage from extraperitoneal rupture of the uterus; (4) an intra-abdominal catastrophe such as volvulus of the bowel; or (5) a combination of (1) and (4) or of (1), (2), and (4). The cause of the distension may be difficult to assess. Retroperitoneal haemorrhage would be suspected from the history of the labour and speculum examination under a good light. If the diagnosis is still in doubt intestinal decompression for twelve hours should be attempted. If dramatic deflation does not follow, it would be advisable to do a laparotomy. The error in the above case was in performing a small suprapubic incision for suspected peritonitis instead of a laparotomy. Even if a diagnosis of peritonitis is reasonably certain it seems preferable to do a laparotomy so as to exclude any associated abdominal condition.

GIFT OF OXYGEN INSTALLATION TO HOSPITAL

A complete installation for oxygen and nitrous oxide has been presented to the Royal Infirmary of Edinburgh by Colonel S. J. L. Hardie, chairman of the British Oxygen Company. It incorporates three miles of copper pipe-line running to various parts of the building, and has 342 points, including points at bedsides in the wards where oxygen can be obtained, and in the theatres, for oxygen and nitrous oxide. There are two manifolds, one for the surgical side and the other for the medical, where big cylinders are housed in banks of four. If a bank of four oxygen cylinders begins to run low an automatic warning is given, a reserve bank of four cylinders comes into operation, and the four exhausted cylinders are replaced by four full ones, which in their turn become the reserve. Normally the cylinders require replacement every three or four days. Oxygen can be obtained at the bedside only when the valve attached to the ward has been turned on by the sister in charge. The oxygen is administered through a mask of American pattern, leaving the patient's mouth free, so that he can eat if necessary while breathing oxygen through the nose. At the opening ceremony the thanks of the managers to Colonel Hardie were expressed by Mr. John R. Little, chairman of the Royal Infirmary Board.

SOME FACTORS AFFECTING THE INCIDENCE OF POST-ANAESTHETIC VOMITING

BY

RUSSELL M. DAVIES, M.R.C.S., D.A.

Anaesthetist to an E.M.S. Maxillo-facial Unit; Honorary Anaesthetic Registrar, Westminster Hospital

The purpose of this article is to bring forward, with the aid of illustrative series of cases, some facts about post-anaesthetic vomiting which are well recognized, and some which I think have been less well recognized in the past. I shall try to show that the incidence of post-anaesthetic vomiting is modified by such factors as the anaesthetic used, the operative procedure, sex, etc., in a manner which does not seem to have been fully realized hitherto.

The cases making up these illustrative series are drawn from the anaesthetic records of the Westminster Hospital and from personal records obtained in the E.M.S. maxillo-facial unit to which I am attached.

Figures given regarding the incidence of post-anaesthetic vomiting vary widely according to their source, and also according to the observer's view as to when true post-anaesthetic vomiting begins and when it ends. The figures quoted below are from unselected series (except where otherwise stated), and represent anaesthetics, anaesthetists, and surgical procedures of every type and degree. The record is absolute—i.e., the patient who vomits once after the first post-operative drink is said for the purpose of obtaining these figures to have vomited once. In addition I have visited all cases in these series, whether referred to directly or indirectly, in an effort to eliminate any varying personal factor that might well arise if more than one investigator had been concerned.

First, taking as a basis 1,000 consecutive cases, the following figures for the incidence of post-anaesthetic vomiting were obtained:

Nausea only..	2.6%
Vomited once only..	15.7%
Vomited 2 to 5 times	20.9%
Vomited more than 5 times in less than 18 hours	6.5%
Vomited more than 5 times in more than 18 hours	0.8%

These degrees will be referred to as N, 1, 2, 3, and 4.

Secondly, it was decided to take four anaesthetic sequences: nitrous oxide, oxygen, and ether; pentothal, nitrous oxide, and oxygen; pentothal, nitrous oxide, oxygen, and ether; and pentothal, cyclopropane, nitrous oxide, oxygen, and ether. In all the series 100 consecutive cases of each anaesthetic sequence have been taken (see table on opposite page).

Series II and III.—It will be seen from the table that, as might be expected, the use of nitrous oxide, oxygen, and ether produces the highest incidence of post-anaesthetic vomiting. But it is rather surprising to find that the preliminary addition of pentothal sodium (the dose varying from 3.5 to 12 c.cm. of 5% solution) reduces the incidence by almost 20%. From the work of Seeley, Essex, and Mann (1936) this effect might well be considered possible, but that it is so great is indeed surprising.

Series IV.—The next effect that stands out is that, contrary to the opinion of some anaesthetists, the addition of cyclopropane to the anaesthetic sequence appears to have little effect on the post-anaesthetic vomiting rate. This may be because a large proportion of these patients suffered only a relatively small degree of surgical trauma; but this may well be offset, at any rate in part, by the fact that

Table showing Incidence of Post-anaesthetic Vomiting when using Four Different Anaesthetic Sequences, compared with that of 1,000 Consecutive Cases

Series	No. of Cases	Nausea N	Vomiting 1	Vomiting 2	Vomiting 3	Vomiting 4	Total N, 1, 2, 3, 4	Total 1, 2, 3, 4	Female	Male	Female Vomiting	Male Vomiting
I. General...	1,000	2.6%	15.7%	20.9%	6.5%	0.8%	46.5%	43.9%	—	—	—	—
II. Gas, oxygen, and ether...	100	3%	17%	31%	11%	0%	62%	59%	67	33	46 (68.6%)	15 (45.5%)
III. Pentothal, gas, oxygen, and ether...	100	6%	15%	20%	5%	0%	46%	40%	46	54	26 (56.5%)	14 (26%)
IV. Pentothal, cyclopropane, gas, oxygen, and ether...	100	0%	17%	21%	4%	0%	42%	42%	25	75	14 (52%)	28 (39.6%)
V. Pentothal, gas, and oxygen...	100	1%	10%	10%	6%	1%	28%	27%	61	39	23 (26.5%)	4 (10%)

most of them underwent an anaesthesia of more than average duration—averaging 72 minutes against 36.5 minutes.

Series V.—It is admitted that in this series the average duration of anaesthesia was less and the degree of surgical intervention also less than for Series II and III. It should, however, be stated that this series included all extra-abdominal procedures with the exception of cranial surgery, and also cases of less severe low intra-abdominal procedures. In addition, while the average duration of anaesthesia was 36.5 minutes, the longest when using this sequence was 175 minutes, while 60 to 90 minutes was considered a figure worthy of only passing note.

Another point is that of the 23 females who vomited 14 had undergone minor gynaecological procedures such as dilatation of the cervix, curettage, application of radium to the cervix, etc. If all cases of females undergoing such procedures are excluded the figures obtained become:

Nausea only (N)	2%
Degree 1	10%
" 2	6%
" 3	4%
" 4	1%

showing a reduction of 6% in the higher post-anaesthetic vomiting rates. The percentage of all females vomiting was 23. Thus it really does seem that the presence or absence of minor gynaecological cases in a series for which the post-anaesthetic vomiting rate is estimated has an appreciable effect on the figures obtained. This point will be referred to later.

Sex Incidence

It has been generally recognized that males tend to vomit less than females, but the difference is rather greater than expected. In Series II the ratio was 68.6 females to 45.5 males; with the addition of pentothal sodium it became 56.5 to 26 (see table). It will be noticed that the preliminary administration of pentothal sodium has a more pronounced effect in males than in females. A reason for this is suggested below.

Effect of Operation

While not dealing with this subject as fully as may seem advisable, it is interesting to note the effect of two types of operation.

Operations on Nose, Nasopharynx, and Mouth.—The figures obtained for 100 consecutive cases are as follows:

Nausea only	5%
Degree 1	24%
" 2	16%
" 3	4%
" 4	5%

These figures are comparable to those quoted for the general series of 1,000 cases, in spite of the fact that the patients' ages ranged from 2 to 70 years, and that it is a common remark that "patients are always sick after tonsillectomy." It appears that there is little truth in this remark.

Minor Gynaecological Operations (e.g., dilatation and curettage, etc.).—For 100 consecutive cases it has been found that the figures obtained are as follows:

Nausea only	4%
Degree 1	26%
" 2	22%
" 3	16%
" 4	3%

This gives the high incidence of 67% of post-anaesthetic vomiting—startlingly high seeing that pentothal played a part, even an entire part, in the anaesthetic procedure of nearly all these cases. This fact becomes more interesting when comparison is made with a shorter series of similar cases in which no pentothal sodium was used; it was then seen that the incidence of post-anaesthetic vomiting was only slightly greater (71% as against 67%). In a series of minor gynaecological operations, all of which included dilatation of the cervix, the post-anaesthetic vomiting rate was 64%, a figure which suggests that the factor causing the raised vomiting rate is the dilatation. Hence it appears that in these cases the anaesthetic given has comparatively little effect on the incidence of post-anaesthetic vomiting. This may well explain the relatively smaller decrease in the figures obtained for females in Series II and III as compared with the corresponding decrease in the case of males.

Treatment

The treatment of post-anaesthetic vomiting, while not within the scope of this article, requires one or two notes. It is as much pre-operative as post-operative. The co-operation of the nursing staff in reassuring the patient can bring about a most gratifying reduction in the figures obtained. The usual lines—absence of food in the stomach, pre-operative glucose, fluids, and avoidance of excessive purging—may be followed with success. Various authorities (Minnitt, 1932; Smith, 1934) suggest the combination of glucose with insulin. Smith found that 2 oz. of glucose given with 5 units of insulin pre-operatively, followed post-operatively by 4 oz. of glucose rectally with 5 units of insulin, reduced the post-operative vomiting rate by 50%. Premedication should be suitable and adequate, and be combined with the administration of a basal hypnotic. In this connexion attention should be drawn to the fact that the substitution of omnopon for morphine in the premedication reduces the incidence. Individual susceptibility to morphine appears to be a very definite entity. Adequate doses of atropine or hyoscine will prevent secretion, and possible swallowing, of ether-impregnated saliva and mucus. The effect of the barbiturates has been noted.

The post-operative supply of fluids in all cases in which fluid loss during operation has been in any way excessive, whether by actual blood loss or by sweating, will also reduce the incidence of post-operative vomiting. The rectal or even oral administration of normal saline to the point at which the patient complains has proved to be an effective measure, which may be further enhanced by the addition of glucose.

The patient should be moved as little as possible on his return to bed. He should be placed in the right lateral position, and be allowed to recover in peace, a careful watch being kept to prevent any obstruction of the airway. Apart from any other consideration, anoxaemia seems to be a pronounced predisposing factor in the causation of vomiting. Post-operative sedation should be applied, and the use of suppositories—e.g., nembutal—should not be forgotten.

Vomiting which is actually occurring may be treated by a variety of remedies. Drinks of hot water, to which 10 to 15 grains of sodium bicarbonate may be added, strong hot black coffee, Lugol's iodine, and sips of champagne all have their measure of success. Lenevitch (1892) advised washing out the stomach with warm alkaline solution (sodium bicarbonate). Though suggested at such a relatively early date, this line of treatment has proved most efficacious, especially in cases of persistent vomiting.

Summary

The incidence of post-anaesthetic vomiting in 1,000 consecutive cases is compared with that in four series, each of 100 cases, in which a different anaesthetic sequence was used.

The effect of sex and of certain surgical procedures on the incidence of post-anaesthetic vomiting is shown, particular reference being made to oro-nasal and minor gynaecological operations.

Lines of treatment for this condition are suggested.

My thanks are due to Dr. I. W. Magill for his advice on the Westminster Hospital cases and in the preparation of this article; and to Dr. John T. Hunter since my transfer to an E.M.S. unit.

Medical Memoranda

Leiomyoma of the Stomach with Ulceration

Although cases of leiomyoma of the stomach have not infrequently been reported in the literature, the following case is considered worth recording in view of the fact that the nature of the tumour was diagnosed pre-operatively, and because some light may be shed on the kind of ulceration occurring in conjunction with these tumours.

CASE REPORT

A lighterman aged 65 was admitted as an emergency, having had a severe haematemesis. Shortly after admission he vomited more bright red blood. His haemoglobin was found to be 30%. He had a history of intermittent indigestion for fifteen years, each attack lasting for from two to three months, and the periods of freedom from pain lasting for as long as two years. There had been no vomiting or loss of weight, and the pain had never been severe. Three weeks before admission there had been a small haematemesis, but since then, until admission, no abdominal pain.

On examination there were slight tenderness in the epigastrium and extreme pallor of the skin and mucous membranes, but otherwise no abnormal physical signs were seen. A transfusion of three pints of blood was given, and the patient improved considerably. X-ray examination performed a month after admission, when the haemoglobin was 68%, revealed a large filling defect high up on the anterior walls of the stomach. Rugae were obliterated over the filling defect, which was well circumscribed and well defined. No niche, crater, or spasm was seen.

In view of the x-ray findings a diagnosis of a benign tumour of the stomach was made, and partial gastrectomy was performed on March 18, 1941. In order to section the stomach

above the tumour it was necessary to remove about three-quarters of that organ. The gastrectomy was of the modified Polya type. No glandular enlargement was found in the abdomen, and tissues surrounding the stomach were healthy and free from adhesions. There was no indication on the peritoneal surface of the nature of the tumour, but its mobility within the stomach suggested that it was benign. After an uneventful recovery the patient was discharged on April 8, with a haemoglobin of 105%.

The pathological report on the specimen (see Fig.) was as follows:

Macroscopic Examination.—The stomach is enlarged, the rugae on the body being well marked. There is a firm growth at the cardiac end in the anterior wall near the lesser curve. The growth is oval, measures 2½ by 1½ inches, and appears to be insinuated between the mucous and serous layers. Its borders are sharply defined, and the mucous membrane over it is stretched and rugae free. There is an ulcer measuring half an inch in diameter, the margins of the ulcer being sloping and its floor necrotic. The cut surface shows a definitely lobulated structure, many of the lobules showing marked congestion, and giving rise to the effect of a coloured pattern.

Microscopic Examination.—The growth consists essentially of muscular fibres with a whorl-like arrangement. There is, in addition, a fair amount of fibrous tissue derived from areas of resolving haemorrhage. The growth in parts is oedematous and throughout is richly cellular; no significant changes are present in the mucosa beyond congestion and some polymorph infiltration. There is no particular cellular infiltration around the ulcer on the summit. Its walls are sloping, and it appears to be a simple pressure atrophy of the mucosa.

Diagnosis.—Leiomyoma of the stomach.

DISCUSSION

Edwards and Lewis (1940) describe a case of leiomyoma that gave rise to haematemesis, which left the patient with only 30% of haemoglobin. Apart from this case, it would seem that the degree of bleeding in our case was unusually severe. They quote Starr Judd as saying that true peptic ulceration may occur on the surface. The microscopical and macroscopic appearances of our case, together with obliteration of rugae over the tumour, strongly support the view that ulceration was due to pressure atrophy. In view of this it is rather surprising that the haematemesis that ensued was so severe. The cause of the gastric symptoms, which had persisted for fifteen years, remains in doubt. The rest of the stomach mucosa showed no signs of gastritis, nor was it apparent how such a gastritis could result from the presence of the tumour. However, the proximity of the tumour to the cardia could, in view of the size of the tumour, undoubtedly have given rise to the considerable disturbance of the mechanics of gastric digestion, and this might be the explanation.

The recommendation of Edwards and Lewis that local resection is all that is required in these cases is undoubtedly a wise one, except that it is difficult to be quite certain of the nature of the tumour. Moreover, the technical difficulties involved in performing a sleeve resection with the tumour so highly situated would be very considerable.

Reviews

THE EXTRA PHARMACOPOEIA, VOL. I

The Extra Pharmacopoeia. Martindale. Volume I. Twenty-second edition. (Pp. 1,289. 27s. 6d., plus 6d. postage.) London: The Pharmaceutical Press. 1941.

Even in W. H. Martindale's time the *Extra Pharmacopoeia* was a useful book for the doctor, despite the strange comments and views with which Martindale sprinkled it. In the hands of the Pharmaceutical Society, however, the value of the book has increased enormously, and it has now become a sound and reliable work of reference.

It is interesting to reflect on the important consequences which follow changes which at the time seem trifling. When Martindale died the book might easily have passed into the hands of another commercial firm and have become little better or much worse. As it is, it represents perhaps the main channel through which a wide circle of doctors can keep informed of the less important advances in treatment. Important discoveries like that of the sulphonamide drugs force themselves on everyone's attention, but minor progress often receives notice for a week or two in the medical journals and is then forgotten. Doctors for the most part do not read books on pharmacology, and books on therapeutics have surprisingly little to say of our steadily increasing knowledge of new drugs. The *Extra Pharmacopoeia* provides a frequently revised source of information concerning these, which is up to date and which gives references to all the papers from which its abstracts are prepared. Considering that the book has been produced by two pharmacists neither of whom has had any form of medical training, the selection of material is astonishingly good. It is difficult to see how it could be improved.

The book contains a new therapeutic index of diseases arranged alphabetically—in which may be found, for example, burns or Raynaud's disease. Under the disease appear the different agents used in its treatment and the page in the book on which the use of each agent is considered. A doctor, puzzled to know what further steps he can take in a difficult case, might look far for better indications.

All the different substances which have occupied attention in recent years are described; amphetamine sulphate, apple powder, carbachol, cyclopropane, leptazol, nicotinic acid, oestradiol benzoate, pamaquin, penicillin, phemitone, pyridoxine, sulphathiazole, vitamin K may be mentioned in passing. It would be safe to wager that many readers of this *Journal* do not know what some of these substances are: how many know that carbachol is the pre-war proprietary doryl? For it is an additional service of the *Extra Pharmacopoeia* that it calls things by their official names, and makes it possible for any doctor to discover, for example, that allocaine, syncaine, aethocaine, ethocaine, kerocain, neocaine, novocain, planocaine, and sevicaine are different names for the same thing, which should always be called procaine. How wonderful it would be if some benefactor could be found who would present a prize to every doctor who was able to show that he never used a proprietary name when an official name was available! How much money our hospitals would save!

The *Extra Pharmacopoeia* is suffering from obesity in these days and giving those who produce it concern about its format. Can it continue to be a pocket book with all it sets out to contain? We leave its producers to struggle with this problem, asking them some time to enlighten us on the precise relation of Volume I to Volume II. Further, they ought to do something about the general arrangement; acetylcholine, for example, is to be found under the general

heading "*Acidum aceticum*," which is ridiculous. This does not interfere with the usefulness of the book, for the index always puts the reader right. But it is a reviewer's duty to pick at least one hole.

MEDICINE INTERPRETED TO THE PUBLIC

The March of Medicine. No. V of the New York Academy of Medicine Lectures to the Laity, 1940. (Pp. 154. 13s. 6d.) New York: Columbia University Press; London: Oxford University Press. 1941.

Medical science is claiming an increasing share in the planning of life. For such claims to be admitted it is necessary that its achievements and aims should be interpreted by experts to the general public. This task the New York Academy of Medicine has been undertaking for the last five years by a series of lectures given in their comfortable and acoustically perfect theatre. The speakers, avowedly taking Faraday and Huxley as their great exemplars, have tried not only to avoid technicalities so far as possible in their exposition, but also to relate their topic to general problems of living.

This most recently completed series opens with Dr. Myerson's discussion of the inheritance of mental diseases, largely based on the study of monozygotic twins, in which he gives sound reasons for discounting alarmist statements as to the increase in these diseases. But we think our Eugenics Society will be a little staggered by his remark that the term "eugenics" has now become synonymous with sterilization! Dr. Perrin Long follows with a lucid account of the history of chemical warfare against disease in which he mentions the interesting fact that the last of the synthetic sulphonamides—namely, sulphathiazole—contains a ring which in another form goes to make about half the molecule of vitamin B₁. This provides another piece of evidence that chemotherapy has more affinity with the biological defences of the body than was thought at first. Dr. Reznikoff deals with the history of our knowledge of the blood, in which he relates the curious case of Dr. W. S. Thayer's patient who, recognizing that her condition of pernicious anaemia was incurable, decided to indulge her taste for *pâté de foie gras* freely and daily. She lived to a ripe old age, but the significance of her recovery was not then understood. Dr. Hutchings describes the progress in the treatment of mental diseases under the title "*The Ascent from Bedlam*," in which he maintains that the mediaeval Church was largely responsible for the maintenance of an inhuman attitude towards those held to be in demoniacal possession. He gives deserved credit to the Quakers for their establishment of the Retreat at York in 1792, where gentler methods were to prevail under William Tuke. He might have added that Tyson, better known as an anatomist, advocated similar principles nearly a century earlier. Dr. Chevalier Jackson speaks of "*The Romance of Bronchoscopy*," in which he was himself a pioneer. Perhaps the most interesting lecture is that on "*The Story of Viruses*," by Dr. T. M. Rivers, for it is not easy to find such a consistent history of this rapid advance in knowledge. W. M. Stanley's discovery in 1935 of a crystalline protein with virus characteristics called for a fundamental readjustment of our ideas on the origin of life. For some, viruses are the result of retrograde evolution; for others, they are the simplest possible form in which life originally took shape; for yet others, they are merely autocatalytic agents, transitional between the living and non-living. Probably viruses are not all in the same category. He tells the story of Adrian Stokes, who when he was taken ill after carrying out a necropsy on an infected monkey which he had done with bare hands, one of which bore an unhealed wound, said: "I hope it is yellow fever," because that would prove he had found its virus. He was correct, and he died, but not in vain, for

that strain of virus yielded a successful vaccine. These lectures may bring home the fact that the hunt for means of preserving life may be as fascinating as the designing of methods of destroying it, while each has its spice of danger.

Presumably publishers know their own business best; otherwise we would suggest that in these hard times 13s. 6d. was an excessive price for a relatively small book.

PRINCIPLES OF RADIATION THERAPY

The Biologic Fundamentals of Radiation Therapy. A Textbook. By Friedrich Ellinger, M.D. With a preface by Maurice Lenz, M.D. English translation by Reuben Gross, M.D. (Pp. 360; illustrated, 30s. net.) New York: Elsevier Publishing Company, Inc. Distributors: Nordeman Publishing Company, Inc. Obtainable in the United Kingdom from H. K. Lewis and Co.

This book was published in German in 1935, and was an attempt to present the results and problems of radiation biology in such a way as to demonstrate that the therapeutic application of radiant energy depends upon the same basic principles already established in pharmacology. In this English translation the work has been brought up to date by the inclusion of references up to April, 1940.

In a short introduction the principal effects of radiation upon the cell are outlined. Part I, of 118 pages, deals with the effects of x rays and gamma rays upon the various normal tissues, organs, and systems of the body, and then gives a brief account of the changes produced in inflammatory and infectious conditions, and in hyperplasia and neoplasia. Part II gives a short account of corpuscular radiations and the administration of radio-active substances, and includes a note upon radio-active springs. Parts III and IV devote 106 pages to the effects of light, the ultra-violet portion of the spectrum taking the major part of the space allotted. Part V considers the general principles of radiation therapy, as based on the facts derived from experimental radiation biology reviewed in the preceding sections. Radiosensitivity, the time factor, the principal radiotherapeutic techniques, and radiation injuries are among the subjects discussed. A bibliography of 1,100 references to the literature between 1930 and 1940 occupies 47 pages, and there is an index to authors and an adequate subject index.

The author calls his work a textbook, but as such it cannot be recommended; for there is very little critical comment upon the mass of often contradictory observations which have been abstracted, and a sense of proportion between what are generally accepted theories and what are merely wild speculations is almost entirely lacking. Moreover, the English translation is not always happy—for example, "Analogously in humans a burn resulting from an overdose of ultra-violet light was accompanied by a radiation injury in the form of a serious irritation of the stomach, persisting for several months. Overdosage of ultra-violet light, therefore, is by no means a matter to be taken lightly." Misprints are few, and the 79 illustrations have been well chosen and well reproduced. As a reference book to original sources and an aid to further investigations the book will be of value to the specialist.

Notes on Books

Your Teeth: Their Past, Present, and Probable Future, by Prof. PETER J. BREKHUS of the School of Dentistry, Minnesota University, gives in plain language an outline of facts and theories about the teeth of civilized man. As the title suggests, it is intended for public enlightenment, and Prof. Irvine McQuarrie, head of the department of paediatrics in the same university, writes a foreword. Prof. Brekhush dispassionately notes the conflicting views on the aetiology of caries and pyorrhoëa, and concludes that the direct cause of our most common tooth troubles cannot yet be named. The theory he favours—

that decreased functioning is mainly responsible for dental deterioration—is merely advanced as a possible point of departure for future research. In essence the book is a reasoned appeal for proper dental care, especially during childhood, and for intensive research soundly based on the fundamental sciences. In his chapter on the relation of dental to general health the author condemns the injudicious application of the truth embodied in the theory of focal infection, and says that this problem is one that must be solved by close co-operation between patient, doctors, and dentist. His attitude towards biological and mechanical factors in loss of teeth is summed up in this sentence: "By all means let us continue to keep our mouths clean and our bodies well nourished, but let us not delude ourselves that by so doing we can keep our teeth from disease and avoid our periodic visits to the dentist." He holds that the most vital function of dentists is to fill the small cavities in children's teeth, and discusses ways and means for enforcing early, universal, and constant care in this direction. This very readable book on dental hygiene is published by the University of Minnesota Press, Minneapolis, at \$2.50.

Within ten years of its first appearance a fifth edition has been published of Miss I. STEWART'S *Medical Handbook for Nurses* (Faber and Faber, 6s. 6d.). The author is now matron of the Victoria Infirmary, Glasgow, and her book links up instruction given in medical lectures with its practical application at the bedside. As before, the keynote is struck in the opening paragraph: "The medical nurse must work in close co-operation with the physician and with the patient. She shares with the doctor the responsibility for the management of the case. He depends on her for carrying out efficiently the treatment he has ordered, for exercising intelligent observation, and for keeping accurate records." The text has once more been revised in the light of modern advances in methods of diagnosis and treatment, so that the nurse may be aware of special points to be noted and reported.

Die Nervenkrankheiten des Rindes, by a comparative neurologist, Dr. E. FRAUCHIGER, and a veterinary pathologist, Dr. W. HOFMANN, both of the University of Berne, is published in that city by Hans Huber, medical librarian, at the price of 24 Swiss francs. This well-illustrated book on the nervous diseases of cattle is described in the sub-title as presenting "a basis for a comparative neurology of man and domestic animal." It falls into two parts: in the first the anatomy of the nervous system is briefly surveyed, with particular attention to methods of neurological investigation in cattle and their differences from those in men; in the second part the nervous diseases of cattle are set out in detail, with full discussion of their relation to the nervous diseases of other domestic animals, and particularly to those of man. To the student of veterinary medicine the book will give guidance in the far from simple subject of nervous disorders of domestic animals; it should also be of value to comparative pathologists and neurologists.

The Department of Scientific and Industrial Research has issued No. 4 of volume 12 of the *Index to the Literature of Food Investigation*, dated March, 1941 (H.M. Stationery Office, York House, Kingsway, W.C.2, 4s. 6d.). It is compiled by Agnes Elisabeth Glennie, B.Sc., assisted by Gwen Davies, B.A., and Catherine Alexander, B.Sc. The abstracts are arranged along the usual lines in fifteen sections, with an alphabetical key to authors at the end. These periodical indexes are of much value to scientific workers and technologists concerned in the preparation, storage, and analysis of food products and in the safeguarding of food supplies, as well as to those who study the physiological, chemical, and physical changes undergone by food and the bacteriology of ripening and putrefaction. The references in this member of the series run from No. 1448 to No. 2032.

It is good news that a second edition has already been called for of Miss MINNIE RANDELL'S valuable book *Training for Child-birth from a Mother's Point of View* (J. and A. Churchill, 10s. 6d.). The new preface mourns the loss, when the massacre department of St. Thomas's Hospital was bombed, of the gallant Barbara Mortimer Thomas, who had contributed so much to the preparation of the book, especially the photographs. These are

superlatively good, both artistic and informative. The only changes seem to be a few additions to mothers' diaries of their own confinements, some of which portray an enthusiastic interest in the sequence of events, and further reports upon the effects of the physical exercises used. Of the value of the latter there can be no question, for if the mother's interest in the use and control of her muscles has been awakened during pregnancy her approach to labour is much more confident and her own efforts during it become rightly directed. Towards the problem of popularizing such training this attractive book is the best possible contribution. It is up to obstetricians to recommend it, which they can do with confidence because the doctor's authority is upheld throughout.

Preparations and Appliances

ENDOSCOPIC RESECTION OF THE PROSTATE: AN IMPROVED TECHNIQUE

Mr. H. T. COX, M.D.Camb., F.R.C.S.Ed., resident surgical officer, Withington Hospital, Manchester Municipal Service, sends the following account of an improved technique to avoid injury to the external sphincter during endoscopic resection of the prostate.

The generally accepted method of avoiding injury to the external sphincter is based on accurate visualization and localization of the verumontanum with the urethroscope and resectoscope. The small but almost universal incidence of incontinence, together with the reported twenty-fold increase in the sale of incontinence-clamps in America since the adoption of endoscopic resection,¹ shows that this principle is easier to observe in precept than to follow in practice.

Seeing the verumontanum with the urethroscope is no guarantee against cutting beyond it with the resectoscope. Three factors, it would appear, are contributory: (1) The verumontanum is a posterior structure lying exactly in the midline, and therefore must pass out of the field of vision when the resectoscope is rotated. In cutting strips in any position except in the midline posteriorly the verumontanum ceases to be of the slightest value as a landmark, as it cannot be identified. (2) Haemorrhage may obscure the view. (3) When the distal end of the telescope is in actual contact with the prostate a complete "black-out" follows. This I have found to occur in making the initial cuts in those rare cases of prostatic enlargement with marked encroachment into the urethra.

It is for these reasons that I have devised the following technique as a more certain and practical method of avoiding injury to the external sphincter.

Technique and Instruments

The principle embodies a mechanical check applied to the cutting process before the cutting loop reaches the external sphincter. This method depends for its success on the observation of three points: (1) Accurate measurement of the distance between the internal meatus and the verumontanum (the cutting distance) with the posterior urethroscope. (2) Accurate measurement of this distance on the rack of the resectoscope. (3) Fixing this distance on the rack of the resectoscope in such a way as to constitute a mechanical check against overcutting and consequent damage to the external sphincter.

At the risk of adding to the "vulgar ingenuity of gadgets" I have modified the Canny Ryall-McCarthy resectoscope and the Millin posterior urethroscope in order to achieve these objects more easily. These modifications are three in number:

1. A scale graduated in centimetres marked on the resectoscope rack (Fig. 1).
2. A sliding check fitted on the resectoscope rack (Fig. 1).
3. A similarly graduated rack and pinion attached to the posterior urethroscope, which is also fitted with a handle (Fig. 2).

The posterior urethroscope is introduced into the bladder and slowly withdrawn without rotating the pinion until the edge of the prostate at the internal meatus is just visible. The left hand

grasps the handle and holds it stationary; with the right hand the pinion is rotated, thus withdrawing the urethroscope until the verumontanum is visible. The distance the instrument has travelled is the distance from the internal meatus to the verumontanum, and is shown in centimetres on the graduated scale of the rack. This is read off, and the same distance is marked and fixed on the resectoscope rack with the sliding check. The resectoscope is thus set for each individual patient before the cutting process is begun.

Two further points require emphasis. It is essential to make absolutely certain that each cut starts at the internal meatus. It is therefore advantageous to leave the most prominent part of the prostatic ledge at the internal meatus until the end of the resection, thus retaining an easily identifiable landmark during the operation. For obvious reasons the resectoscope sheath must

FIG. 1.—Resectoscope with graduated rack and sliding check (A) set for a cutting distance of $2\frac{1}{2}$ cm.

FIG. 2.—Posterior urethroscope with pinion and rack graduated in centimetres from its ocular end.

be held stationary during the resection—i.e., it must not be permitted to move in or out.

A further advantage of this method is evident in two-stage resections. The distance between internal meatus and verumontanum is written on the case sheet at the conclusion of the first operation; at the beginning of the second operation the instrument is set at this distance, thus avoiding the necessity for further localization of the verumontanum.

Results

Previous to the adoption of this technique three cases of partial incontinence were encountered. One patient returned his penile clamp three weeks after discharge from hospital, normal micturition having been recovered. The other two remained control before discharge. Since adopting the technique I have performed forty-eight resections, removing a total of 537 grammes from twenty-seven patients (average weight per patient, 19.8 grammes). Three were carcinomatous prostates, two fibrous (5 grammes each), and the remainder adenomatous. In no case has there been even a transient degree of incontinence. The protection of the external sphincter has been complete. The results of the resection have been most satisfactory: many patients without hope of survival after suprapubic enucleation have been restored to normal micturition.

I express my sincere thanks to Mr. Southam, senior consulting surgeon, and to Mr. Holt and Mr. Simmons for permission to operate on their cases; to Dr. Greenwood, medical superintendent, I am indebted for permission to report them. Messrs. Chas. F. Thackray Ltd. of Leeds have kindly made the necessary modifications to the instruments, in spite of the exigencies of the present conditions.

HOSPITAL PROVIDENT SCHEMES

Lord Nuffield has yet once more made a far-sighted contribution to the hospital services of the country. As announced last week, he has created a Provident Guarantee Fund of £150,000 with the object of increasing the formation of mutual insurance schemes to assist the middle and professional classes to meet the cost of illness requiring specialized or surgical treatment in hospital pay-beds or nursing homes. The fund will be available to guarantee the financial solvency of provident schemes in provincial areas, in Scotland, and in Northern Ireland. The condition of the guarantee is that the schemes are approved by the trustees of the fund and provide "substantial cover" for subscribers and the members of their families on a contributory basis; no doubt a model scheme will be constructed. Such provident schemes, it is hoped, will "have a close alignment with the area Hospital Councils which have been created in various parts of the country, and with which the Nuffield Provincial Hospitals Trust is associated."

With the exception of the British Provident Association, which supplies a grant in aid to its contributors and applies no income limit, provident schemes are of only recent development. There can be little doubt that the system of mutual insurance as a method of paying for specialized medical and surgical services is the most satisfactory way of meeting the great financial strain which the cost of such treatment throws upon the middle classes. But lack of funds and of beds in voluntary hospitals has barred progress on these lines. In 1934 the British Medical Association, anxious to promote the provident scheme movement in connexion with pay-beds, held a conference at which all interested bodies and existing provident schemes were represented. Out of this conference came the publication of a model provident scheme with draft memorandum and articles, and the establishment, with the financial aid of the B.M.A., of a National Federation of Provident Associations, to which Mr. W. Hyde acted as honorary secretary. Since then the Federation has worked consistently for the aims established. So far as the Provinces are concerned, Lord Nuffield's generous benefaction may be looked on as placing the National Federation on a firm financial footing, under a different name but with the same energetic and able secretary, Mr. Hyde. It is as well to recall that the model scheme agreed on in 1934 provided full cover for professional fees and nursing-home charges in the event of illness requiring specialized institutional treatment for persons within defined income limits and paying agreed annual premiums. An excellent example of this scheme working in practice was the Oxford and District Provident Association, Limited.

Simultaneously with the publication of Lord Nuffield's scheme there appears an announcement about another provident scheme. The short published statement in the Press records the appointment by King Edward's Hospital Fund of a committee under the chairmanship of Sir Bernard Docker to sponsor a provident scheme designed to cater for the requirements of the middle and professional classes in the London area. Such a scheme, for middle-class and professional persons within a defined income group, was practically complete just before the outbreak of war. Voluntary hospitals and their staffs had been consulted, and at a meeting of London consultants called by the B.M.A. general approval was given to the outline of the scheme, which was to give full cover for specialized treatment in beds set aside for the purpose. In the larger London hospitals the resources of a scheme with reasonable premiums would not meet the cost of private beds. This being taken into account, the scheme was evolved on the assumption that the members would be accommodated mainly in a new type of bed, intermediate between the general ward bed and the private bed.

At the outbreak of war it was agreed by the King's Fund subcommittee that the prevailing conditions made the moment highly inopportune to proceed with the plan. First and foremost was the fact of the complete reorganization of London hospitals and the redistribution of their staffs. Hospital accommodation in London was severely restricted. Many members of the voluntary hospital staffs were employed whole-time or part-time at hospitals at which they had held no peacetime appointments, and at council hospitals which admit for treatment any patients without distinction of class or income—that is, in circumstances which would make their participation difficult if not impossible owing to the absence of the necessary kind of bed. Since the beginning of the war there has, of course, been a further restriction on hospital accommodation as the result of air raids, and with the prospect of a renewal of the aerial bombardment of London further loss of hospital space is to be expected. There has also been an increase in the number of persons coming within the scope of the E.M.S.—that is, persons who cannot be required to pay private fees or have private fees paid in respect of their hospital treatment. These facts—the limited number of available beds, the difficulty of arranging at the present time for a new type of bed, and the inability of many of the voluntary hospital staffs to take part in the scheme—would seem to have been ignored by the King's Fund committee in deciding, despite the advice of its subcommittee, to launch the scheme now. Finally, it would be a great pity if, at a moment when the relations between the voluntary and local authority hospitals are to be worked out in accordance with the Government's hospital policy announced a fortnight ago, the former were to introduce a scheme which might be suspected to have as its principal aim the grouting of the financial buttress of the London voluntary hospitals. There would seem to be something unreal about the securing by the voluntary hospitals of money for a service which could not be made fully available to those who under the scheme would expect to receive it.

THE INFLUENCE OF CHOLINE ON ANIMAL METABOLISM

The influence of choline—a normal constituent of mixed diet and derived from lecithin and other phospholipids present in animal fat—on animal metabolism was discovered as a result of the observations, by Fisher¹ and by Allan and co-workers,² that depancreatized dogs maintained on insulin and certain mixed diets developed large fatty livers. When fresh beef pancreas was given in the food the livers did not become fatty. Hershey³ found that crude egg-yolk lecithin also prevented the development of fatty livers in depancreatized dogs. Best and others⁴ observed that normal rats could be used as test animals for these investigations, which thereby became greatly simplified. These workers at once showed that purified lecithin was lipotropically active (i.e., having an affinity for fats), and that choline was the active component of this substance.^{5,6} By using simple diets of purified food substances, fatty livers were produced by (1) giving some easily available form of neutral fat, which produced the so-called "fat" fatty livers; (2) giving large amounts of cholesterol in the diet, which produced the "cholesterol" fatty livers; and (3) including large amounts of sucrose and very little protein in the diet. Best and his collaborators in Toronto⁷ and Channon and his collaborators in Liverpool⁸ showed that all these forms of fatty liver could be prevented by giving choline to the rats.

The influence of casein as a lipotropic substance could not be ascribed to the negligible amount of choline which it contained. Comparison with the activity of other proteins led to the conclusion that certain amino-acids influence the deposition of fat in the liver. Curtis and Newburgh⁹ had shown that cystine produced fatty livers. Tucker and Eckstein¹⁰ found that a recently separated amino-acid—methionine—had exactly the opposite effect. Singal and Eckstein¹¹ observed that arachin, a protein deficient in methionine, was without lipotropic action, but the addition of methionine made it as active as caseinogen. Du Vigneaud and others¹² and Griffith and Wade¹³ have also noticed an interrelationship between choline and the ratio cystine/methionine of the diet. Amino-acids without lipotropic activity are serine, lysine, aspartic acid, phenyl-alanine, alanine, proline, hydroxyproline, histidine, valine, leucine, and arginine. Tyrosine has slight activity. The two authorities on this subject—Best of Toronto and Channon of Liverpool—accept the antagonistic action of methionine and cystine, though the latter believes it is at least possible that the lipotropic activity of casein is due to an unidentified contaminant. Synthetic homocholine has been found to be more effective than choline itself, and certain analogues

of choline (e.g. betaine) have been found to have some effect. Other substances similar to choline but without the hydroxyl group have been found to cause an increase in liver fat and even to be extremely toxic.

Some workers still claim lipotropic activity in pancreatic extracts which is not due to the presence of choline or protein. One such preparation has been called lipocain; it seems to affect depancreatized dogs but not normal rats. György and Goldblatt¹⁴ found that the addition of vitamin B₁₂ to the diet of rats used in experiments on acrodynia killed many of their rats after 11 to 15 days. They subsequently realized that the diet was deficient in choline, and concluded from microscopic examination of the liver and kidneys that vitamin B₁₂ accentuated the influence of a deficiency of choline by causing necrosis of the renal cortex.

Choline does not prevent the deposition of fat in the liver in cases of phosphorus poisoning (though it may hasten its dispersion when the administration of phosphorus has ceased), nor when injections of anterior pituitary extract have been given. Choline and some analogues reduce the deposition of cholesterol esters in the liver as well as true fats. Though choline prevents the accumulation of fat in the liver, it increases the deposition of fat in other parts of the body. McHenry¹⁵ has shown that the actions of choline and vitamin B₁₂ on the weight of young rats are complementary. Much aneurin and little choline result in the deposition of fat in the liver. Lack of choline also seems to affect the liver's ability to store glycogen, but whether this is the result or the cause of the accumulation of fat is not known. Best⁷ suggested that choline accelerates the oxidation of fat in the liver. Raab and Strauber¹⁶ have indeed found that giving choline by mouth to normal dogs produced an increase in blood sugar and keton bodies, but no increase in blood fats. It has been suggested, but not proved, that choline is changed to lecithin or some other phospholipid to remove fat from the liver, but fat can also be removed from the liver by fasting. Perlman and Chaikoff¹⁷ by the use of P³², have shown that choline given in the diet increases the rate of turnover of phospholipids, the rate being proportional to the amount of choline given. Its possible relationship to the methionine/cystine ratio of the protein of the diet is still more obscure. There is no evidence to show whether it acts independently of this ratio or whether it is interwoven with it.

ANATOMICAL STUDIES ON HUMAN TUBERCULOSIS

Repeated morbid anatomical observations often serve as a brake to theoretical speculation by the clinician. New methods of investigation—for example, post-mortem radiography—or the study of environmental factors such as general malnutrition associated with war may also throw fresh light on hitherto accepted data. This is especially true in the field of tuberculosis, and

the excellent morbid anatomical studies¹ of Kornel Terplan, formerly a disciple of Ghon and now working at Buffalo, are therefore welcome. These studies were carried out at necropsy on 698 children between the ages of 5 weeks and 18 years, and on 289 adults up to 90 years of age, a relatively small percentage of whom died from chronic pulmonary tuberculosis. A careful anatomical dissection was accompanied by complete histological examination of all lesions, full use being made of post-mortem radiography.

Dr. Terplan found tuberculous lesions in 5.9% of children under 6, and in 19.4% of those between 7 and 18. In most fatal cases death was due to haematogenous dissemination, with tuberculous meningitis following more or less closely the establishment of a caseous pulmonary lesion; this was found in both infants and older children. In three cases intrabronchial progression had occurred almost simultaneously with haematogenous dissemination, which, though decidedly less marked, nevertheless led to meningitis. In three others with wide intrabronchial spread in direct connexion with primary lesions, haematogenous seeding was minimal or absent; such intrabronchial spread may closely mimic the features of the so-called adult type of tuberculosis. In yet three other cases meningitis as almost the only manifestation of haematogenous tuberculosis followed exacerbation of the tuberculous process within one or more lymph glands close to an old calcified lesion—examples of endogenous lymphoglandular "reinfection." Other of Dr. Terplan's cases showed that the primary tuberculous infection may occasionally restrict itself to one or more typical parenchymatous lesions without any anatomical evidence of further spread to regional lymph glands. Complete healing of these primary foci may even more rarely be followed by additional reinfection from without, which may cause haematogenous dissemination and death.

In the 289 adults tuberculous lesions were absent in only 3% of those over the age of 50. Terplan says it was futile to attempt to estimate the absolute age of calcified or osseous tuberculous lesions, as Sweeney has done.² In seven adults between the ages of 19 and 63 there was a recent primary complex with intrabronchial and/or haematogenous tuberculosis. In sixteen others, aged 28 to 80, necropsy revealed incidental typical primary complexes in the caseous, fibro-caseous, or partly calcified state. These changes pointed to a late primary infection, and, contrary to views expressed elsewhere, lymph-gland involvement was extensive, and thus did not appreciably differ from that seen in primary complexes among children. In ten adults two tuberculous complexes of very different structural ages were found, each in a different lung, or, in a few cases, in a different lobe—one in a completely stony state, the other, of recent structure, mostly caseous or partly calcified, the caseous lesion resembling a typical primary complex. Thus the finding of multiple calcified lesions does not necessarily indicate that they were formed simultaneously by a single primary infection. In yet two other adults, aged 33 and 54, who showed calcified remnants of an old tuberculous lesion, a relatively recent

lesion of true exogenous reinfection led in one case to death from haematogenous dissemination and in the other to intrabronchial progression (haematogenous seeding being also present). Finally there were cases among the adults, as among the children, of healed primary foci without glandular involvement; in some of them there were typical reinfection "primary" complexes.

It is evident that primary infection is by no means rare among adults at all ages, and that it follows much the same course as it does in children. The primary nature of the lesions and not the patient's age determines the anatomical characters of the lesions. Further, some exceptional features in primary infections and in reinfections are yet common enough to call for care in dogmatizing on epidemiological observations based on tuberculin or radiological surveys. It is still premature to attempt to correlate humoral data (such as allergy) with anatomical findings in the classification of tuberculosis, as has been done by Ranke.

Dr. Terplan draws attention to the confusion in the use of certain terms. Thus the "primary focus" is the reaction of tissue to, or the structural change brought about by, the tubercle bacillus at the site of the first recognizable lesion, and the term should not be used for tuberculous lesions in lymph glands. A primary focal lesion is always present (in the lung or intestine and very rarely in other organs such as the tonsil), though it may not be recognized from casual anatomical observation. The term "primary complex" should be applied to the primary focus, wherever it may be, and to the tuberculous lesions in the corresponding lymph glands near the focus—to the two component lesions together. Any other lesions, except those developing in immediate association with the components of the complex in its active state, should be referred to as post-primary lesions. The term "reinfection" should mean a new infection with bacilli from without, and should exclude "any formal genetic relationship to the primary infection"; it does not imply that the former—primary—infection must have been completely healed anatomically and biologically. Terplan wishes the term "endogenous reinfection" to be abandoned; it clearly refers to endogenous exacerbation—that is, to a local recurrence or reawakening of an older, usually quiescent, process, with or without evidence of further lymphatic, haematogenous, or intrabronchial spread. "Superinfection," if used at all, should be applied only where an additional infection from without can be proved in an individual who still harbours an active tuberculous lesion. Terplan criticizes the statements on childhood tuberculosis by J. A. Myers,³ to whom development of sensitivity to tuberculin is the criterion of "reinfection," and the misleading use of the terms "childhood type" and "adult type" by Opie and others—terms that "have dominated the teaching of tuberculosis in the English-speaking countries in recent years." More recently Miller⁴ and Pinner⁵ in America, and Kayne, Pagel, and O'Shaughnessy⁶ in England, have stressed that if these terms were dropped we should better understand the pathogenesis of tuberculosis.

VIRUSES AND INFECTION THROUGH THE SKIN

For many years it has been common practice to administer antirabic vaccine to persons whose hands have been licked or otherwise contaminated by the saliva of dogs suspected of being rabid, despite the fact that there is no very convincing experimental evidence that rabies virus readily passes through the unbroken skin. There is, however, growing evidence that certain other viruses may readily pass through the skin. Bauer and Hudson¹ infected rhesus monkeys by rubbing yellow-fever virus on the apparently unbroken skin. However, no attempts were made to exclude the possibility that the monkeys scratched the virus into the skin or transferred it to mucous membranes. Findlay² subsequently showed that when the virus of Rift Valley fever is placed on the lightly scarified skin of the mouse fatal infections are produced. The viruses of yellow fever and Rift Valley fever, however, are normally transmitted by the bites of insects and may thus be specially adapted to passage through the epidermis. More recent evidence shows that viruses not usually carried by insect vectors may penetrate the skin. Findlay and Stern³ showed that when lymphocytic choriomeningitis virus was rubbed on the lightly scarified skins of mice the animals did not exhibit apparent infection, but the virus could be recovered from their spleens and kidneys: when the same virus was rubbed on the lightly scarified skin of two rhesus monkeys one had a febrile reaction. Subsequently Shaughnessy and Milzer⁴ demonstrated that guinea-pigs developed the typical picture of the disease when the virus was placed on skin so lightly scarified that blood was not drawn. Shaughnessy and Zichis⁵ have now shown that lymphocytic choriomeningitis virus is able to infect the guinea-pig when it is merely placed on the intact skin. The most consistent results were obtained when the virus was suspended in broth, while virus suspensions in water and saline possessed lower infectivity, a fact which may be correlated with the greater filterability of viruses suspended in broth as compared with suspensions in distilled water or saline. Although minute abrasions, not visible with a hand lens, may have been present in the skin of the guinea-pigs, such a condition would naturally be a factor encountered in any normal skin. These experiments suggest that other viruses may be able to pass through what is to all intents and purposes normal skin.

TUBERCULOSIS IN WALES: A GRIM OUTLOOK

In the annual report for 1940-1 of the King Edward VII Welsh National Memorial Association Dr. D. A. Powell, the principal medical officer, makes the following arresting statement, whose implications should give much food for thought: "The stress of war is showing itself most wearily in an increasing shortage of staff, and the position in our institutions is so serious that all our beds—and the need for them was never greater—cannot be utilized. The shortage affects all sections of staff, particularly nursing, and the restrictions of the Ministry of Health on the recruitment of Civil Nursing Reserve personnel to tuberculosis institutions are not making things any easier. The demand for beds is so clamant, however, that every attempt is made to keep the maximum number going in spite of the risks that have to be run, the uninformed criticisms which may have to be refuted, or, worse still, the possible commission of admitted blunders that will have to be condemned." Is it really all there is to be said about this deplorable

situation (blame for which cannot, however, be laid at the door of the association itself)? Almost half the patients seen at the dispensaries had a positive sputum on fir examination, and of these nearly 60% were classified as advanced cases. Dr. Powell adds: "When it is remembered that owing to our shortage of beds most of the cases have to wait for a long time, and therefore the ground still further before they can be admitted, the grimness of the position can be appreciated." Owing to the need for economy in the use of paper the present report is in abridged form, and it was not possible to include separate reports by medical officers, but among the points brought forward by them and summarized by Dr. Powell the following must be mentioned: (1) "As regards rationing, the consensus of opinion is that so far no definite effects upon patients have been detected, but it should be borne in mind that the patients themselves, thanks to their self-sacrifice of other members of the family [our italics] particularly the womenfolk, would probably be the last to feel the pinch." (2) An increase has been noted in the incidence of tuberculous glands in the neck, and particularly of tuberculous meningitis. (3) Fear is expressed about the importation of new infection into isolated hamlets and rural districts by evacuees, etc. (4) Disquieting signs of trouble arising from the effect of war work upon young women are evident in the occurrence of an unusual number of cases of pulmonary tuberculosis, many of an acute type, in a certain factory. Finally, as in previous years we note with satisfaction the great increase in the use of radiography, and deplore once more the inadequate contact examinations: in 1940 nearly 16,000 new cases were examined for the first time, but only just over 1,800 new contacts. This represents even a smaller ratio than in the previous year. In view of this, and in view of the disquieting shortage of bed accommodation, it appears premature to stress, as is done by Lord Davies in his address to the Board of Governors, the immediate application of mass radiography on a large scale. Mass radiography should be introduced, and the sooner the better, but must be preceded by the provision of adequate beds for those discovered to have active disease and of facilities for the full investigation of the large number of people with suspicious radiographs.

EPIDEMIOLOGY OF AMERICAN Q FEVER

For some years a febrile infection has been known to occur in Queensland chiefly among dairy farmers and slaughterhouse men. The cause of this disease was found by Burnet and Freeman⁶ to be a rickettsia, which was termed by Derrick⁷ *Rickettsia burnetii*. A series of mild or subclinical laboratory infections was described both in Melbourne (Burnet and Freeman⁸), where no natural infections have ever been reported, and in Brisbane (Smith, Brown and Derrick⁹). The epidemiology of the disease in Australia would seem, however, to be associated with infection of a tick, *Haemaphysalis numerosa*; the Queensland bandicoot *Isodon urocyon* is a reservoir, though other wild animals in Australia may play a similar part.

In 1938 Davis and Cox¹⁰ described a filter-passing agent from ticks *Dermacentor andersoni* collected near Nine Mile Creek in Montana. The organism was described by Cox and classified as belonging to the rickettsia group, the name *Rickettsia diaporica* being proposed (Cox¹¹). Dye

reported the first proven human infection in America in a laboratory worker, and pointed out that there was a close similarity between Australian Q fever and the disease produced by the rickettsia isolated from ticks in Montana.⁹ Both Australian and American workers are now agreed that the diseases in the two continents are identical, and that the rickettsias are two strains of one and the same organism. In these circumstances it seems inadvisable to apply two names to one and the same organism, and since *Rickettsia burneti* was proposed by Derrick² on January 7, 1939, while the name *Rickettsia diaporica* did not see the light of day till October 6, 1939, it follows that the latter should be dropped and the former used. If a distinction is desirable between the Australian and American strains the latter would become *Rickettsia burneti* var. *americana*.

At first sight it would seem that American Q fever must rank as an ordinary tick-transmitted rickettsiosis. Recent events may, however, modify this view. Two cases are recorded by Hesdorffer and Duffalo¹⁰ of patients who gave no history of tick bites, though it is true they had been in the woods in Montana. One case, however, occurred in October and the other at Christmas, when it was most unlikely that ticks would be present. A striking event in the history of this infection is recorded by Hornibrook and Nelson¹¹ from the National Institute of Health at Washington, D.C., where an institutional outbreak of Q fever occurred among the workers, from whom Dyer and his colleagues¹² were able to isolate *Rickettsia burneti*. Altogether there were fifteen proved cases of infection among the 153 persons employed in one building, but there were no instances of infection in the wing of the building where work has been in progress on Q fever since the spring of 1938. Whether or not this unit served as a focus of infection is open to question, for the personnel of the unit itself was spared and the cases were widely distributed throughout the building. No valid evidence was obtained that personal contact or the intervention of an arthropod vector was in any way responsible for the transmission of the disease. The most remarkable feature of the institutional outbreak was a central pneumonia or pneumonitis, detected only on x-ray examination. This condition was also present in the cases described from Montana. It is of particular interest, because in the past year or two a number of cases have been described from widely scattered areas in the U.S.A. in which pneumonitis was associated with clinical symptoms like those found in proved cases of American Q fever. This infection may therefore be not uncommon, with a distribution far wider than was at first imagined.

THYROIDECTOMY IN DIABETES INSIPIDUS

The diuretic effect of desiccated thyroid in nephrosis is well known, but its relation to water balance in general has not been completely understood, though some association with the pituitary has been suspected. As long ago as 1889 Rogowitsch showed experimentally that the cells in the anterior lobe of the pituitary increased after thyroidectomy, and this was later confirmed clinically. In 1920 Strauss described a case in which diabetes insipidus gradually disappeared as the patient developed myxoedema. It was also found that experimental diabetes insipidus in dogs was checked by thyroidectomy but returned when thyroid extract was administered. In cats the same sequence of events occurred after cutting the supra-opticohypophyseal tracts. It would appear, therefore, that in the relation

between the thyroid and pituitary the former is a factor in the regulation of water balance. This suggested to H. Blotner and E. C. Cutler¹ to apply such observations to the treatment of diabetes insipidus by total thyroidectomy, which they accordingly carried out on three patients in 1935; since then reports of four other cases have appeared. Of the first three two were relieved; these happened to be cases of post-encephalitic Parkinson's disease. The remaining one was unaffected, but there was reason to believe that accessory thyroid tissue was present. Of the second group two were relieved, both post-encephalitics, and in these the parathyroids were also removed. Administration of thyroid re-established the polyuria but dinitrophenol did not, showing that the relapse could not be attributed merely to raising the basal metabolic rate. The authors' conclusion is that in the normal person there is a balance between a diuretic principle in the anterior lobe of the pituitary and an antidiuretic one in the posterior lobe, and that the former acts through the medium of the thyroid. This does not conflict with the observations of S. W. Ranson and his associates to the effect that the supra-opticohypophyseal tract controls the secretion of the posterior lobe hormone. Blotner and Cutler accordingly advocate total thyroidectomy in cases of diabetes insipidus associated with post-encephalitic Parkinson's disease. Though they have established a point of theoretical interest and importance, the number of successful cases is too small to be a basis for recommending such a drastic procedure.

ECONOMY IN PHENOL AND ITS DERIVATIVES

The attention of the Ministry of Health has been drawn to the need for economy in phenol and certain allied compounds, and a circular on the subject was issued on October 10 to all hospitals connected with the Emergency Medical Service. Medical officers are requested to be as sparing as possible in the use and prescription of the following substances and preparations containing these substances: (a) phenol; (b) salicylic acid, acetylsalicylic acid (aspirin), sodium salicylate, and methyl salicylate; (c) phenolphthalein. Steps are being taken through the machinery of the E.M.S. to ensure that medical officers, nurses, and dispensers are made aware of this need for economy, and we are asked by the Ministry to give the widest publicity to the matter, so that the profession as a whole may co-operate in limiting the use of phenol and its derivatives.

The Lister Medal for 1942, which is awarded in recognition of distinguished contributions to surgical science, has been granted to Professor Evarts A. Graham, professor of surgery in the Washington University. He will deliver the Lister Memorial Lecture in 1942, or later, under the auspices of the Royal College of Surgeons of England. This is the seventh occasion of the award, which is made by a committee representative of the Royal Society, the Royal College of Surgeons of England, the Royal College of Surgeons in Ireland, the University of Edinburgh, and the University of Glasgow.

We regret to announce the death of Mr. H. Edmund G. Boyle, F.R.C.S., late senior anaesthetist to St. Bartholomew's Hospital.

THE FUTURE OF MENTAL HEALTH

BY

KARIN STEPHEN, M.A., M.R.C.S.

The report of the Mental Health Committee of the B.M.A., recently published, comes at an opportune moment when problems of post-war reconstruction are beginning to be discussed. As was pointed out in a leading article in the *Journal* of August 23 (p. 269), there are a very large number of patients, both old and young, who require care and treatment from medical practitioners trained in mental medicine, and our present facilities are by no means adequate to deal with them satisfactorily. The demand for reconstruction, which exists already and will gather strength as victory approaches, may give the opportunity for a great step forward in psychological medicine, on the results of which success in many of our other plans for a better world may depend—even success in the prevention of war itself. But plans must be well laid, and schemes which only sound like an advance and lack the essentials must not be allowed to go forward and be embodied in legislation. So we must not blind ourselves to the difficulty of our task. The possibility of setting up the model scheme for the treatment of mental illness described in the B.M.A. "Grey Book" makes an excellent start as regards the general organization required, but the scheme does not deal with the crucial question of how the doctors who are to carry it out are to be selected and trained. The success or failure of the whole plan, however, centres round this vital point, since even the best organization cannot give good results unless those who are to administer it are capable of performing their task. The selection and training bristle with difficulties.

Two Types of Doctor to Train

There are two types of doctor to consider, whose training involves quite distinct problems. In the first place there are the specialists who propose to devote their whole time to the actual practice of psychological diagnosis and psychotherapy: in addition there are the general practitioners, who would need only to know enough about psychological medicine to make a provisional diagnosis, since they could then refer the cases to the specialist for a further opinion and for treatment when this was required.

Taking the case of the specialists to begin with, how should they be trained? Stress has rightly been laid on the length and complexity of the treatment in mental illness and the knowledge and highly specialized skill required. There is also the further difficulty, when any scheme for setting up the right kind of medical service in mental medicine comes to be worked out, that the question as to what sort of training is suitable to qualify a doctor to undertake this difficult task is a matter of hot dispute between the different schools of psychotherapy. Even if this dispute could be settled, a further problem would arise in choosing the candidates to be trained, since not everyone who has a medical degree possesses the type of personality needed for making a good psychotherapist. The problem is indeed formidable, but if we are prepared to be bold it may not be insoluble.

There is one point, at any rate, on which, in spite of all their other differences, most schools of psychotherapy now agree, and that is that any doctor who means to specialize seriously in this branch of medicine must himself undergo some form of personal treatment before he can hope to have the self-knowledge which is requisite for the proper understanding and safe handling of his patients. This would mean that the training of psychotherapists would involve a double procedure, of which the intellectual understanding of psychopathology, which can be learnt from books, lectures, and clinical demonstrations and tested by examinations, would only be the less important, though still necessary, half. The now-established D.P.M. would supply this part of the training, provided more extended facilities for obtaining the necessary teaching were made avail-

able, and provided also that the syllabus were revised to cover the new requirements. As it stands the syllabus appears to be over-weighted with neurology, since, although the standard here is admirable, the nervous system is, after all, only one among the many systems of the body which are liable to disturbance from psychogenic causes and in which it is important for the psychiatric specialist to be able to make a differential diagnosis between organic and psychogenic disease. This problem of differential diagnosis does not appear to be given sufficient weight in the D.P.M. as it stands at present: even in respect of the nervous system, the important question of psychogenic pain, for instance, seems to be neglected. The questions on psychopathology are not all up to the same high standard. Some of them, however, would afford an excellent opportunity of testing the candidate's knowledge, but much would depend on who the examiners were and whether their own knowledge of psychopathology was wide enough to enable them to pass an adequate judgment on the candidate's attainments.

Personality and Psychotherapy

Assuming, however, that the revised D.P.M. will provide for the intellectual instruction of the doctors who wish to qualify as specialists in psychological medicine, we now come to the still more difficult half of their training. It was pointed out in the above-mentioned leading article that the personality of the doctor is important in psychotherapy, and that it would only be worth while accepting for training those whose personality was suitable. This is an important point, and it may well be that some of the discredit in which psychotherapy is apt to be held results from neglect of this wise precaution. It would thus be necessary to set up a very carefully chosen selection board to decide on the suitability of candidates.

In selecting these candidates it would be important to take into consideration their previous development, much as one does in taking a psychiatric case history: how were they regarded at home, at school, by their associates; how did they get on with their work and in their social and emotional lives; also, why do they want to take up this exacting career of psychotherapy? A strong inclination for this work may be a favourable indication in many cases; but unfortunately it would seem that a number of people are attracted to the study of abnormal psychology because they themselves are in difficulties; and, while some degree of psychoneurosis does not appear to be any absolute bar to the successful practice of psychotherapy, the work is definitely interfered with if, as sometimes happens, the doctor is really seeking for the solution of his own difficulties via the treatment of his patient.

Choosing the Trainers

Skilful selection along these lines would eliminate the wrong type of candidates and ensure that only suitable personalities were chosen; but this would only be the first step, since, as has been said, it is now fairly generally agreed that even the right type of personality needs further modification and further insight before the candidate is fit to undertake the highly responsible and specialized task of psychotherapy. For the second half of the training—the personal experience of being treated, aiming at producing the necessary character development and self-knowledge which the psychotherapist requires even more than he requires theoretical knowledge—a completely new system would have to be created, and it will be extremely difficult to find reliable trainers in sufficient numbers to cope with the demand. The same board as was appointed to select the candidates would no doubt supply the most suitable trainers also, but there will be the utmost difficulty in arriving at any agreement as to who are themselves qualified to undertake this central task. The success or failure of the whole plan for the development of psychotherapy will probably turn on the constitution of this selecting and training board. The supporters of the different schools of psychotherapy will dispute hotly about its constitution; each will perhaps be partly right, at least in its condemnation of the others. The ideal personnel for such a responsible task as this board would be called upon to undertake actually does not exist, either in this country or elsewhere. Something very far short of perfection must be accepted, but who is to choose this board which will itself have to select and train the candidates? *Quis custodiet ipsos custodes?* Should

it be made up by proportional representation from the various rival schools? Few, it must be confessed, would feel sanguine about the success of such an approach to our problem. How, then, should the board be chosen? Should it be elected democratically by the whole body of competent psychotherapists now practising? Should it be reconstituted at frequent intervals; and by what methods? These are most difficult questions, and yet it is absolutely vital that the best answer should be found, and the people most nearly suitable for the task should be chosen.

At least we know this much, that the same requirements as are essential in the candidates held to be suitable for training in psychotherapy would be needed in the members of the selection and training board: to begin with, the right personality, itself a somewhat rare quality, together with a thorough intellectual grasp of psychopathology. But even these, alone, are not sufficient. The further requirements are that the personality should have been modified, and the intellectual understanding expanded so as to include the emotional realization which comes with deepened self-knowledge and full insight, and which is achieved only when the doctor is able to recognize how this theoretical knowledge applies, not only to patients, but to himself. Only such realization can bring about the resolution of personal conflicts, the full character maturity, and the intellectual clarity and objectivity that are needed to complete the personality and theoretical-knowledge qualifications required for the difficult tasks which even the ordinary psychotherapist, and still more the members of the selection and training board, will be called upon to undertake.

No doubt the standard set by such requirements is appallingly high, but nothing short of this standard will enable psychotherapy to fulfil its possibilities, and if we content ourselves with too little our attempts at reconstruction will fail.

Programme for the G.P.

Turning now to our second question—the training in psychological medicine suitable for general practitioners—here the requirements are different, and the standard; both in personality and in knowledge, need not be so exacting. What these doctors require to know is principally how to recognize the presence of psychogenic factors in their patients' illnesses. They would need to be able to make a rough differential diagnosis between the following:

(a) Straightforward organic illness and so-called "functional" illnesses the symptoms of which often closely resemble those of true organic disease, but which seem to be concerned merely with changes of function, and in which no true organic lesions or irreversible alterations of the bodily organs can be demonstrated: the group, in short, of the hysterical conversion symptoms which may show themselves in the form of psychogenic disturbances either of over- or under-action of any of the bodily systems (nervous, vasomotor, alimentary, urogenital, respiratory, endocrine, or metabolic, etc.), together with those other disturbances of function—e.g., the numerous physical symptoms seen in anxiety neurosis—which appear to be the bodily effect of abnormal emotional conditions rather than symptoms of true conversion hysteria.

(b) Illnesses whose origin is wholly or partly psychogenic but in which organic lesions or irreversible bodily changes may occur—e.g., gastric and duodenal ulcer, mucous colitis, asthma, again possibly some kinds of endocrine and metabolic disturbances, and many more, some already familiar to psychological medicine, others no doubt still to be discovered.

(c) Complicating psychogenic factors in illnesses of purely organic origin.

Lastly, they would need to have a working knowledge of the common symptomatology and diagnosis of the psychoneuroses and psychoses. This programme is formidable enough, but quite a lot of the ground could be covered adequately by instruction in the hospital out-patient departments and psychological clinics if these were staffed by really competent teachers. It is possible that at any rate the clinical papers of the revised D.P.M. could be so framed as to test these candidates as well as the specialists, for whom the whole examination would be primarily designed.

As regards the papers devoted to psychopathology, however, it is highly questionable whether the general practitioner should be required to know much about the theory of psychopathology itself. A strong case could be made for confining this instruction to those who mean to specialize in psychotherapy. The others, with only at best an intellectual knowledge of the subject, would not be qualified to treat patients, and attempts to apply theoretical knowledge, without the personality qualification, self-knowledge, and insight demanded of the specialist, might only prove harmful to patients and bring psychotherapy into disrepute.

ANGLO-SOVIET MEDICAL COMMITTEE

A meeting of the vice-presidents and executive committee members of this organization was held at the house of the Royal Society of Medicine on October 8. The President, Sir Alfred Webb-Johnson, P.R.C.S., took the chair, and in opening the proceedings expressed the satisfaction of the committee at the visit of Sir Charles Wilson, P.R.C.P., to Moscow; he was sure that on Sir Charles's return his advice would be invaluable. The honorary secretary, Dr. Elizabeth Bunbury, reported that in the four weeks since the inaugural meeting a good deal of ground-work had been done. The provisional committee had already forwarded some material to the Soviet Union, including a complete set of the *Bulletin of War Medicine*. A very full summary of recent work on typhoid vaccines, together with an offer to supply good Vi strains for culture, had also been sent. The letter published in the *Lancet* and *British Medical Journal* on September 20 had brought in about seventy-five offers of help. Twenty-six doctors knowing Russian had offered to translate for the committee. A new and immediate problem had arisen—that of giving advice on the purchase of medical supplies for the U.S.S.R. A number of lay organizations had raised considerable sums of money, and there was urgent need for a co-ordinating body on equipment. The President thought that the Anglo-Soviet Medical Committee should accept responsibility for giving advice on medical supplies, but should not be responsible for making purchases or for arranging shipments. Mr. Somerville Hastings agreed about the urgency of this matter; he had found that there were many rival organizations in the markets for the available drugs and equipment. Lord Horder thought that a representative of the Red Cross should be asked to join the committee. Lord Dawson agreed with the President that the committee should advise only and should endeavour to co-ordinate its work with the Red Cross, the Ministry of Supply, and the Embassy. Prof. Ryle suggested that a letter be sent to the Press stating the committee's preparedness to give advice to lay organizations on such questions. It was agreed to set up a subcommittee to explore the situation and make recommendations for action.

BRITISH PHARMACOPOEIA

British Equivalents for Proprietary Drugs

The General Medical Council has approved names for certain substances which are now being produced, or are likely shortly to be produced, by British manufacturers, in some instances under licences granted by the Comptroller-General of Patents, Designs, and Trade Marks. These substances have hitherto been known under other names, which are given below together with the names now approved. The question of including these substances in the *British Pharmacopoeia* is under consideration and, if any of them is included, the intention is that the approved name given below will be its official title. It is hoped that the early publication of these approved names may lead to their general adoption.

Approved Name
Amethocaine hydrochloride
Menaphthone
Pethidine hydrochloride
Soluble phenytoin

Sulphacetamide

Other Names
Decicaine
2-methyl-1:4-naphthoquinone
Dolantin
Epanutin; eptoin; sodium &
phenylhydantoinate; solacoin;
soluble dilantin
Albicid

Reports of Societies

FAT AND CARBOHYDRATE METABOLISM

The presidential address in the Section of Therapeutics and Pharmacology of the Royal Society of Medicine was delivered on October 14 by Dr. R. D. LAWRENCE, whose main subject was the interactions of fat and carbohydrate metabolism. He prefaced it by a tribute to his predecessor in the chair, the late Sir William Willcox, and by what he called some sobering reflections, to which his controlled experiments in diabetes had led him, on clinical research.

The Dangers of Hypothesis

Dr. Lawrence said that in medical research, especially in the rapidly progressing subjects of metabolism and chemistry, any guess that was made—or any hypothesis, if that word was preferred—would generally be wrong. The best they could strive to do was to establish a new fact, which as often as not was merely a new interrelationship of two already known phenomena. Any total explanation or any large hypothesis built up around this new fact would almost certainly be proved later to be wrong or only half right. Such imaginative processes were fascinating and inevitable to the inquiring scientific mind, and were integral stepping-stones in research, but it was all too easy to become biased in favour of one's own hypothesis, to plan a series of experiments to yield confirmatory results, and to harden one's mind against contradictory results and thus perpetuate error. Another great difficulty was the impossibility of reading and digesting all old and new work on the problem. Such width of reading and knowledge seemed possible only to a whole-time worker in a limited field.

For his own part, working in a field in which error was almost inevitable, he had at least tried to guard himself against two tempting "crimes" in clinical research: (1) the premature publication of improperly controlled and half-proved facts which it might take a whole generation to disprove; and (2) building up wide generalizations and hypotheses, even on true evidence, which were bound to lead others astray for a long time.

Diabetic Metabolism

No one (said Dr. Lawrence) had produced a very clear picture of either fat or carbohydrate metabolism alone. It was certain that plants and animals built up reserves of fat from carbohydrate, but the reverse process was still unproven in animals. In normal human metabolism fat-carbohydrate interaction was always hidden, and laborious studies of the respiratory quotient could give only broad indications. In starvation and diabetes, however, these interactions were more obvious. The last few years had brought to light important new experimental facts which had changed and simplified their ideas regarding diabetic metabolism. It was clear that either carbohydrates or fat could be used as the main source of body fuel, but their metabolic course was very different in both chemistry and function. Carbohydrate storage was poor; on the other hand the fat stores of the very obese could provide fuel, theoretically at least, for about six months. Carbohydrate appeared to be the preferential fuel of muscular activity. This contrast between fat and carbohydrate was also manifest in the blood and internal organs, especially the liver. The carbohydrate-fed liver showed a high percentage of glycogen and a small amount of fat, but as soon as carbohydrate was not available the glycogen virtually disappeared and fat accumulated. The liver might become palpably enlarged, the spleen might enlarge, with lipid deposits; also, at any time when the switch-over occurred from a carbohydrate to a predominantly fat metabolism ketone bodies accumulated in the blood and urine.

The Ketone Bodies

Ketone bodies occupied a most prominent place in the diabetic picture, not only theoretically but in the therapeutic aspect. It had now been shown conclusively that ketone bodies were burned peripherally independent of carbohydrate oxidation. He considered this fact of such importance as to warrant men-

tioning the experimental evidence. Under the commonest normal conditions of diet carbohydrate was predominantly and preferentially used for metabolism, but as soon as carbohydrate was cut off or became insufficiently available for the needs of metabolism depot fat went to the liver and was metabolized to ketone bodies, which then provided adequate fuel for the body. Ketosis was specially harmful when it appeared suddenly, as when insulin was cut off from a fat diabetic dog or human patient. He had been often struck by the ease with which a patient who had supported a severe gradual ketosis succumbed to a sudden one which seemed to be milder than the condition he had tolerated for a long time. Normal men and animals developed an intense ketosis when first changed over to fat metabolism. It appeared that, as with other functions commonly in abeyance, it took some time for the full and efficient use of the new function to be developed. Insulin in the diabetic and sugar in the starved animal switched the metabolism straight back from fat to carbohydrate, and ketonuria usually disappeared in from three to six hours.

He next described an unusual case of diabetic lipaemia in which the lipaemia proved to be dependent on the blood-sugar concentration and not on the diet. From this it was suggested that diabetic obesity was produced directly by hyperglycaemia. The reason why the case he described showed a raised blood fat as the result of a high blood sugar was that this patient had lost the power of subcutaneous fat storage.

Diabetes and Obesity

A very large proportion of diabetics were obese before the manifestation of the symptoms of their disease. This applied not only to the middle-aged who had been obese for a long time but also to many people who developed diabetes in their second, third, or fourth decade. For a year or two before the diabetes came on they might be weighing ten or twenty pounds more than they had ever done before, but as soon as the symptoms got worse that weight disappeared. The explanation often offered was that obesity in some strange way had overstrained the pancreas. He thought this was to put the cart before the horse. These people had been mild diabetics, and it was the hyperglycaemia which had made them fat. Later, as carbohydrate tolerance failed and excretion of sugar rose, they developed all the typical symptoms and lost their excess of weight. It seemed to him that if enough insulin were given to utilize a sufficient food for an active life and to prevent ketosis, but insufficient to prevent a raised blood sugar for several hours a day, then from this high blood sugar obesity developed with which it was very hard to cope. There appeared to be two types of lipaemia—anabolic and katabolic, the latter being the usual condition observed in the disease, and the former a condition which, apart from a few hours after a heavy meal, was never really visible.

Finally Dr. Lawrence spoke of various lipotropic factors such as choline. He described the occurrence of large fatty liver in diabetic children, and the therapeutic possibilities of these factors in such a condition. His personal experience of the syndrome of "hepatomegalic dwarfism" was very slight. He had seen many diabetic children with enlarged liver, but as a rule this was only temporary and quickly disappeared with adequate treatment. In only two out of 500 cases had he seen a persistent and severe development of this syndrome. It was a syndrome which could not be mistaken—the protuberant belly, the halted growth, the infantile face and hands. These cases were strenuously treated with choline without the slightest effect on the liver, but after a few weeks in hospital with zinc-protamine-insulin and some other insulin the liver was brought down. He had also tried lipocae extract, introduced and used in America, but without any useful result, and in his view this condition of hepatomegalic dwarfism was due to bad diabetic control.

There was much evidence, but little exact information, pointing to the influence exercised by other endocrines and even vitamins on both fat and carbohydrate metabolism. The pituitary gland had clearly a most important influence. But in conclusion Dr. Lawrence said that it was quite probable that one day it would be proved that his disjointed remarks on this occasion were well-meaning but erroneous guesses in a difficult subject.

Correspondence

Head Injuries in Motor-cyclists

SIR.—In his important communication on "Head Injuries in Motor-cyclists" (October 4, p. 465) Prof. Hugh Cairns stresses the importance of a crash helmet in minimizing the effects of head injuries in accidents to motor-cyclists.

In 1914, when medical officer to the Brooklands track, I had a profile view of a motor-cycle crash during a race, and through the clerk of the course I was put in touch with the manufacturers of police helmets and designed a crash helmet that was used for the Tourist Trophy Isle of Man Race of that year. The reply of the medical officer attending that race to my inquiry as to how the helmet had worked was brief and to the point: "Every year the humdrum of medical practice in the Isle of Man is relieved by interesting concussion cases in our hospital from the Tourist Trophy Race; this year, thanks to your damned helmet, we have had none."

After the last war, although changes were made in the shape of the helmet, its principles remained the same. It was built of layers of linen soaked, I believe, in shellac, and this was attached to a lining of web slings which were sometimes padded and which fitted closely to the rider's head. The lining came down over the back of the neck and was continued on to a chin strap which retained the helmet in position. This helmet was practically unbreakable, and even after most severe impacts, in which the rider escaped without injury, I have seldom seen more than a partial tear slightly separating the individual layers from each other. The surface was polished and undentable, so that almost any impact due to a fall was deflected. It came into use in 1920, and during the following sixteen years I admitted only two head injuries to hospital from accidents sustained by motor-cyclists when riding at Brooklands and wearing a properly constructed helmet. Both of these were exceptional, one man being thrown with great force at right angles against a vertical face of concrete, and the other striking the side of his head when his motor-cycle fell over sideways when he was too high up the banking. Both these men, one unconscious for eleven days and the other for five weeks, made complete recoveries and returned to their full ordinary work.

Unfortunately, I have kept no record of the number of crashes that happened at Brooklands, but except for five Saturdays in each season when the track was in use for other purposes motor-cycle races were held nearly every Saturday afternoon from April till October. It was seldom that at least one rider was not flung from his machine in these races, and there were other crashes there in the course of the year at long-distance races. Every week the track attendant reported to me one or two accidents during the almost daily practice on the track where nothing more serious than trivial abrasions had been received, and there were, of course, numerous accidents at other meetings in various parts of the country, again with a notorious absence of serious results.

It became obvious that any projection on the surface of the helmet was dangerous, and the wearing of badges stuck on to it was prohibited. At one meeting three men were hurt who were wearing a new type of helmet, the base of which was encircled by two parallel strings which prevented it from splaying outwards and helped to retain its shape (see Fig. 6 in Prof. Cairns's article); these cords slowed the helmet when skidding on the trackway. I reported the accidents to the Auto-Cycle Union Committee, and they were at first rather sceptical about their being due to such an apparently trivial cause, but it was soon found that men wearing these helmets did get hurt when they were thrown from their machines, and one was killed in the Isle of Man, where the friction of the cords against a wall slowed the passage of his head against it, allowed his body to swing round and fracture his cervical spine.

I do not know if there is more than one pattern of helmet issued to Army motor-cyclists, but those I have seen have not embodied the lessons learnt in track racing. They had an outer shell separated from an inner lining by a layer of felt. The outer shell was hardened, but a moderate impact could crack it, dent it, or otherwise damage it, and the underlying felt being soft the whole helmet would be compressed and crushed, with

serious or fatal associated injury to the skull. I recently saw one of these helmets that had been flattened by a motor-cycle passing over it when the wearer was lying on the ground; his skull was crushed and the brain extruded, an injury the Brooklands helmet would certainly have prevented.

I feel that a properly constructed helmet would have resisted the impact that punched out a hole in the outer casing referred to in Prof. Cairns's Case II and prevented the severe damage noted in Case III. Case IV shows how easily the helmet fractured, as the impact took place at only 25 m.p.h., and in many accidents at Brooklands the riders crashed at over 100 m.p.h. In Case V the dent on the helmet showed how inefficient was the surface hardening, which allowed dangerous localization of the force of the impact: that could never happen on the hard undentable Brooklands model.

I am fully in agreement with Prof. Cairns that in the cases he has cited the helmet worn has lessened the effect of the impact, but I am sure that the injuries described would have been still further minimized by a model conforming more closely to the principles of that so long in use at Brooklands. It would be a pity if his valuable article tended to suggest that enough had been done in the matter of head protection and that finality had been reached in the construction of crash helmets.—I am, etc.,

Weybridge, Oct. 15.

ERIC GARDNER.

Increase in Fatal Road Accidents

SIR.—The opening paragraph in your leading article on head injuries in motor-cyclists (October 4, p. 481) may give the impression that the number of adult pedestrians killed in road accidents in wartime has not increased. It is a fact that during the second twelve months of war there was a slight decrease in the number of such road users killed as compared with the first twelve months of war, but the fatalities still exceeded 4,000, or nearly 2,000 more than in pre-war years. In fact, of the 5,300 additional victims in the first two years of war, some 4,300 were pedestrians, 550 were passengers on vehicles, and 400 were motor-cyclists.—I am, etc.,

Oct. 7.

J. A. A. PICKARD,
General Secretary, Royal Society for the
Prevention of Accidents.

Science and World Order

SIR.—The article on the British Association conference on "Science and World Order" (October 11, p. 516) stated that "the plan was to have a few papers to be discussed by British scientists . . . but men of science of other nationalities . . . proffered contributions." This does not correspond to the facts. On the contrary, the British Association advertised this conference as international, formal invitations were sent to foreign Governments (I have one such invitation on my desk), and in all official messages and communications to the daily papers the presence of delegates of all nations was stressed.

I agree, however, with your contributor that the conference was amorphous; it was on the whole, in my opinion, a failure. And this because, although widely advertised as scientific and international, it was neither. It was not scientific because, although some scientists took part, the "headliners" were distinguished politicians, diplomats, and a famous novelist. It was not international because, although in all governmental communications "famous scientists from all nations" were to be made welcome, no place was made for foreign delegates in the work and discussions, and on the whole few Allied and foreign scientists participated.

For this reason the main scientific problems of these terrible days have not been touched. The disaster of the European populations dying of starvation and threatened by epidemic has been mentioned by only one speaker, Dr. Kodicek, and his speech was, of course, not in the newspaper headlines. This, however, is the great problem to be solved by the scientists of to-day, and I suggest the convocation of another conference, purely scientific and really international, to concentrate on its solution. I hope that British scientists will take the lead in this. It should not be said that science is once more divorced from reality, and that to the danger of the civil populations of the Nazi-occupied countries it responded only with empty phrases and post-war Utopias.—I am, etc.,

London, W.1, Oct. 15.

A. P. CAWADIAN

Clinical Manifestations of Exposure to Tetrl and T.N.T.

SIR.—The article by Drs. J. Hilton and C. N. Swanston (October 11, p. 509) raises points of special interest at the present time, when the early recognition and treatment of industrial disease are of great importance to medicine and the national production effort.

Two of the conditions described in this article—namely, toxic jaundice and aplastic anaemia—carry a high mortality, yet from the authors' description of toxic jaundice this in its early stages may simulate the benign cyanosis which they also describe. We are not clear how the authors differentiate (a) "mild cases in which the patients are otherwise well" and who "remain in contact under observation" from (b) those cases of symptomless cyanosis which "herald" toxic jaundice; and whether the absence of symptoms is the criterion employed for allowing the cyanosed worker to remain in contact.

In our experience, T.N.T. contact workers showing either lilac or ashy-grey cyanosis may admit, on inquiry, to no symptoms. We initiate treatment, and according to the clinical findings arrange for contact or non-contact work in each case. With this treatment improvement is visible in the course of a few days, and we have been struck by the fact that in this initial phase of recovery the worker notices his improved condition, and realizes by contrast his previous ill-health. He comments spontaneously on the fact that he has been feeling "giddy," "dopey," "drunk," "tired out," for some time now. We have found in these workers a mental and physical torpor, insidious in onset, which they neither realize nor express.

The routine treatment we employ, and which so far has proved successful with these patients, has been outlined with illustrative cases in detail by Dr. J. H. Watson in a paper as yet unpublished. Briefly, it consists in the early use of vitamin C and sodium carbonate, supplemented where necessary according to the type of poisoning present. The patients remain at work and receive treatment daily at the factory surgery, the choice of work being determined by our clinical findings.

The investigation in all cases comprises a clinical examination of the patient, with a careful note of their work history and previous occupation, a blood count and differential white cell count, Webster's urinary test for T.N.T., and urinary tests for bile and urobilinogen. In certain cases a spectroscopic examination of the blood is made. Any patient who does not show a normal blood and urinary picture is temporarily removed from contact. Hitherto we have been fortunate in having encountered no cases of toxic gastritis as described by Drs. Hilton and Swanston.

In conclusion, we should like to endorse their statement that factory medical officers are anxious to co-operate with general practitioners in helping to diagnose these conditions. We believe that the detection and prompt initiation of treatment in workers showing the earliest signs of T.N.T. toxæmia will arrest the course of a condition which may otherwise progress to a fatal issue, or incapacitate the worker for a long period.—We are, etc.,

E. K. WILLIAMS.
G. H. THOMSON.

Oct. 15

SIR.—I was interested to note that Drs. J. Hilton and C. N. Swanston (October 11, p. 509) had found common gastric signs and symptoms in exposure to tetrl (or C.E.) and T.N.T. I consider the probable explanation is that both C.E. and T.N.T. stimulate the appetite. There are a certain proportion of the new entries to the factory who suffer from dyspepsia, and the stimulation of the appetite by C.E. and T.N.T. thereby aggravates the already established gastric condition. Many of these people have previously suffered from total or intermittent unemployment, with resultant dietetic restriction. The better economic state, superadded to the stimulated appetite, requires in those people a short time to rectify. At the same time many of these people have to travel long distances to work, and either through distaste for breakfast or lack of time to take breakfast the result is that they have to start work on an empty stomach. We experienced this difficulty, but excellent canteen arrangements solved this, and I believe we outstrip all other factories, as 65% of our employees take a hot cooked meal each day at the factory canteen, whereas at other factories the highest total is 25%. We have here none of this so-called T.N.T. gastritis.

Here it is interesting to note that Viscount Chetwynd during the last war reduced his gastric cases from 11.6% to 0.7% by suitably feeding his employees.

Regarding methaemoglobin, I have made an extensive investigation which has been cross-checked by experts, and we have not discovered, up to date, methaemoglobin. In some cases a pigment resembling sulphaemoglobin has been found. I have been specially interested, as I have wished to connect up whether this condition might be due to the Mackenzie-Wallis nitroso bacillus, which has the power of reducing nitrogen compounds. This bacillus is found in the saliva and the faeces. Splenic dysfunction should not be overlooked. The cyanosis is the mauve or purple cyanosis of sulphaemoglobin, as distinct from the chocolate-brown cyanosis of methaemoglobin.

Regarding toxic jaundice, the high 30% mortality and the fact that recent advances in therapy have not been used in treatment suggest that no progress in the outlook has been made since 1914-18. This is certainly not the case with us, as our mortality for the seven months before the perfection of new methods of treatment was very much less than 30%, but since the standard of treatment we have now attained the results have been that we have had no fatal case in this last six months. The early diagnosis and treatment of what I term the pre-toxic jaundice and the pre-aplastic state is our aim. The pre-aplastic state is a definite macrocytic type of anaemia in which a polymorphonuclear leucopenia is microscopically found.—I am, etc.,

JOHN H. WATSON, M.B., Ch.B.

The Aqueous and Glaucoma

SIR.—Your leading article on "The Aqueous and Glaucoma" (October 11, p. 515) is, I submit, *ex parte* and not in your best judicial manner. Before such definite claims can be made on behalf of dialysis, criticism such as I have brought forward from the outset must be met and answered, not merely ignored. These objections I have summed up in two recent articles, "The Mechanism of Aqueous Secretion in Mammalia" and "The Mechanism of the Intra-ocular Pressure in Mammalia," which appear in the current volume of the *British Journal of Ophthalmology*.

Admittedly dialysis appears superficially as a straightforward physical process. In the eye, however, dialysis cannot take place, for the simple reason that the mechanical—that is, anatomical—conditions are such that it is a physical impossibility. The dialysis of aqueous is, in short, the conception of function operating without a mechanism. This is only one, though I suggest a somewhat fundamental, obstacle to the theory of aqueous dialysis and all its implications.—I am, etc.,

Nottingham, Oct. 13.

THOMSON HENDERSON.

Voluntary Hospitals

SIR.—May I claim two fundamental virtues for the voluntary hospital in addition to those so well presented by your recent correspondents.

I divide doctors into medical artists and medical tradesmen, and the present tendency is for the latter to predominate. I submit that the peculiar mental atmosphere which has evolved in voluntary hospitals tends specially to foster the growth of clinical artistry. The impelling motive in their doctors (and hence in their nurses) is not primarily to earn money or please a committee but to satisfy their individual sense of artistry in every job well done, and if any of the staff can find a better method of alleviation or cure he is gratified in his artistic sense and also by the appreciation of his fellow artists on the staff—especially if the new method is worthy of publication. This spirit of artistry automatically secures the best interests of the patient, for perfunctory medical work can easily satisfy a committee or the lay public. They mistrust striving and originality, preferring a comfortable economical routine, with no complaints or questions asked. Such an atmosphere is deadening to medical aspiration.

My second point is that medical psychologists are constantly preaching the benefit to be obtained from altruistic actions—so cleverly taken up by the Boy Scout's good action every day. Now the voluntary hospital system from top to bottom provides an enormous field for altruistic effort—for each hard-

working member of the lay board down to the humblest subscriber. If all our hospitals were run by the State or municipality the whole of this invaluable and satisfying outlet for altruism would be swept away—a real though imponderable disaster on a national scale. For neuroses batten on selfishness and yield to altruism: the human mind is never satisfied to live for itself alone.—I am, etc.,

Hull, Oct. 9.

FRANK C. EVE, M.D., F.R.C.P.

Tuberculosis Rampant

SIR,—Though I have been practising in England for only three years, I should be glad if you will allow me to make a few observations in your correspondence columns.

Much has been done for tuberculosis in this country, and quite a lot written about "carriers" in the columns of your *Journal*, but still the fight against the tubercle bacillus seems a hopeless one, as the enormous toll shows every year. During my short stay here I have met a few patients with active pulmonary tuberculosis who are allowed to leave the sanatorium if and when they wish. They mix with their friends and relations, and, in one particular case, with a family on whom the patient and his family were billeted—all eating and associating in a common room. Representations to both the sanatorium and local authorities were of no avail, the sanatorium authority declaring he cannot keep a patient in against his will.

The seriousness of such a state of affairs is only too obvious. A patient classified as T.B. II+ with cavities in both lungs was allowed to return to his work because "he was very anxious to go back to work." With a decided increase in tuberculosis, a definite decrease in resistance after two years' war conditions, and the forthcoming influenza epidemics with such potent "carriers" about, one dreads to think how much greater the increase in tuberculosis will be in the near future. More rigid control seems the only answer.—I am, etc.,

A. H. BARTLEY.

Treatment of Haemorrhagic Disease of the Newborn

SIR,—While not claiming "a much wider experience" of the treatment of babies who bleed in the newborn period than Dr. J. J. Robb (October 11, p. 526), I yet venture these comments.

The rational treatment of any patient who bleeds depends, whatever his age, on the cause and the severity of the bleeding. When a newborn baby bleeds it may have a hypoprothrombinaemia, a peptic ulcer, rarely even a thrombocytopenia, or there may be an abnormal condition of the erythropoietic tissues or a severe general infection. This far from exhaustive list may present great difficulties in differential diagnosis. We need at least a full examination of the patient, a complete blood count and study of blood films, and a prothrombin estimation.

Without this information the treatment of bleeding in the newborn baby remains empirical and the assessment of new treatments impossible. The indication for vitamin K is a hypoprothrombinaemia; for a transfusion of whole blood, anaemia. Of the ritual injection of blood, citrated or not, intramuscularly or subcutaneously, whether from a blood relation, male or female, or from a friend of the family, I remain sceptical; there are too many cases where the patient recovers without treatment of any kind.

Haemorrhagic disease of the newborn is a time-honoured label but an insufficient diagnosis. A closer study of these cases is essential before the value of any one method of treatment can reasonably be discussed.—I am, etc.,

St. Albans, Oct. 13.

ALFRED WHITE FRANKLIN.

Organization of E.N.T. Department in E.M.S.

SIR,—Many will have read with much interest the article on this subject by Mr. V. E. Negus (October 11, p. 519). My experience in an E.M.S. hospital—though perhaps less extensive—has been essentially similar to his, and I endorse his views as to the need for a fully developed E.N.T. department in a general hospital of any size. Unfortunately my experience of the need for equipment has also been exactly the same. Mr. Negus writes: "Unfortunately the equipment which I consider

necessary has not been provided. That supplied is insufficient in quantity for the many patients who must be examined, treated, and operated upon in this sector, and is in many instances of a different pattern from that to which my colleagues, my assistants, and I have been habituated. The return of civilians to their war work and of soldiers to their units should not be impeded by lack of equipment. We have had to improvise instruments and use privately owned ones to fill the gap."

Before war was declared, and as soon as I knew that I should be working at an E.M.S. hospital, I began trying to obtain the simpler surgical instruments for the E.N.T. department at that hospital, but unfortunately they have not even now been provided. I wrote many letters to the Ministry, and interviewed personally each of the three Ministers of Health who has held office since the war began, but simple instruments in daily use in every E.N.T. department are still lacking in the hospital in which I work. Mr. X, who chooses E.N.T. instruments for E.M.S. hospitals, may be able to do first-class work with the aid of, or in spite of, the instruments he selects for us, but it does not follow that Mr. Negus or I can do even passable work with them. I can say with truth that since the commencement of the war I have never done an E.N.T. operation in an E.M.S. hospital without using some at least of my own instruments. This may work moderately well if I know beforehand the exact nature of the operations which I have to perform. If I do not, I have either to send for my instruments or postpone the operation to another day—thereby wasting public money.

I wonder if the experience of Mr. Negus and myself has been shared by others.—I am, etc.,

London, Oct. 15.

SOMERVILLE HASTINGS.

Mobile First-aid Posts

SIR,—To-day I had the privilege of being present with a competing unit at a regional competition at Cambridge for mobile first-aid posts from the Eastern Counties. Though beaten by better teams we had a pleasant and instructive day and a valuable opportunity of discussing our work and methods with members of other units. As a result, I should like to comment on some points which seem to me to be important.

1. The present functions of mobile first-aid posts, as I understand them, are: (a) to supplement or replace overworked or damaged fixed aid posts; (b) to set up temporary aid posts in bombed rural areas, or at points where there may be a concentration of casualties beyond the capacity of local services; (c) in case of invasion, to set up advanced dressing stations for civilian, Home Guard, or Army casualties, wherever required.

2. For these purposes equipment is issued in portable cupboards, which have to be dismounted, unpacked for work, and finally reassembled and embarked before moving off. This postulates a sizable room or hall, with suitable lighting and black-out and the expenditure of a good deal of time and exertion.

3. Of the large number of mobile aid posts in the counties represented at the competition a very small percentage has seen active service, though a number of the districts to which they are attached have had their share of "blitz."

4. Now for my own experience. After trying out the method of working described for nearly a year, during which many practices were carried out in village halls, country houses, and industrial works, I was so impressed by the difficulty (a) of finding adequate accommodation, and (b) of getting into action in time for treatment for shock to be of much use, that I acquired a fourteen-seater bus, and arranged permanent fittings for equipment, heating, lighting, and washing, with suitable black-out. We can now arrive at an incident with everything prepared for immediate action, can deal with one stretcher case or three sitting cases at a time in the bus, and can lay out requisites for as many more as may be necessary, for treatment in any room or cottage, however small.

At the meeting referred to this arrangement was rather frowned upon by authority as being a variation from the official technique, but conversation with medical officers of other units gave me the impression of concurrence with my views. I submit that, using methods such as I have suggested, more use might be made of mobile aid posts in urban districts.

to supplement and assist hard-pressed first-aid parties, thereby putting into the collar necks which are worn hairless by straining at the leash of long-deferred opportunity. In the rural work with which I am familiar I am convinced that the ability to arrive ready to work anywhere and to move on quickly, given by the method I now use, outweighs all other considerations.—I am, etc.,

Oct. 12.

C. GRANTHAM-HILL.

"First Aid to the Injured"

SIR,—Would you be kind enough to publish in your correspondence columns the following letter which I am sending to the secretary of the St. John Ambulance Association?

"SIR,—For the last fourteen years it has been my pleasure and privilege to lecture and to examine on behalf of your Association. While I have always thought that your authorized textbook, *First Aid to the Injured*, is extremely satisfactory as a training manual in time of peace, my studied opinion during the last three years has been that it is inadequate in time of war, when the basis of first aid must be simplicity, flexibility, and improvisation. In peace the interval between the accident and the casualty receiving professional attention has been measured in minutes; in war, more particularly during a period of invasion, the interval may be one of days. This is especially true in the rural areas, where the only skilled help available for casualties, even for as long as ten days, may be St. John and Red Cross personnel, working in isolated houses without any surgical supplies, or in the casualty collecting posts of the Home Guard and A.R.P. points and posts with limited supplies of dressings. I would therefore appeal to your Association to consider whether a supplementary pamphlet on 'First Aid in Time of War' should not be considered an urgent and immediate necessity. My tentative suggestion would be that haemorrhage, shock, wounds, fracture, pain, burns, and the evacuation and accommodation of casualties are the necessary subjects for reconsideration, with particular emphasis on the use and abuse of the tourniquet. The immediate reaction of the first-aid student to the treatment of bleeding should not be the tourniquet—it is not a fool-proof weapon. It is my intention to send a copy of this letter to the Editor of the *British Medical Journal* with a view to publication and professional criticism."

—I am, etc.,

JOHN C. HODGSON, M.D.,
Battalion Medical Officer, Kent Home Guard

Oct. 12.

Sulphonamides for Cerebrospinal Fever

SIR,—Dr. N. Mutch, in his article on "A New Sulphonamide" (October 11, p. 503), refers to 154 cases of cerebrospinal fever in Wrexham. May I point out that all of these cases were treated by me at the isolation hospital, and not by "various doctors." With the exception of seven cases, all were treated with sulphonamides. Of these seven exceptions, four were moribund on admission and died within a few minutes. It may be of interest to note that up to date we have had 222 definite cases with twenty-two deaths, or a mortality of 9.9%. Of the 222 cases all except eight were treated with sulphonamides.—I am, etc.,

T. P. EDWARDS, M.D., D.P.H.
Medical Officer of Health and Medical
Supt., Isolation Hospital

Wrexham, Oct. 11.

J. R. Sprague and R. A. Srigley (*Ohio med. J.*, 1941, 37, 843) record four cases of intussusception due to a Meckel's diverticulum. All recovered from the operation, which is remarkable in view of the usual large mortality—56% in children under 5 and 36% in those over 5 years of age. Of the five classical symptoms—(1) sudden onset, (2) projectile vomiting, (3) shock, (4) abdominal mass, and (5) melaena—an abdominal mass was felt in only one case and none of the patients had melaena. Also in contrast with ordinary intussusception the average age of these cases was 13.8 years. In three cases the intussusception was reduced by stripping downward with the fingers, and in the last case a longitudinal incision through the constricting edge of the intussusception permitted reduction.

Obituary

ALEXANDER GOODALL, M.D., F.R.C.P.Ed.

Physician, Royal Infirmary of Edinburgh

We regret to record the death on October 16 of Dr. Alexander Goodall, who was senior physician to the Royal Infirmary of Edinburgh in length of continuous service and in age. He had held office for three years as President of the Royal College of Physicians of Edinburgh, and was for many years lecturer on clinical medicine in the university.

He was born in 1876 at Barr, in Ayrshire, the son of the Rev. Charles Goodall, B.D., minister of that parish, and was educated at George Watson's College and Edinburgh University, where he graduated M.B., Ch.B. in 1898 and M.D. with high commendation in 1901; three years later he was elected F.R.C.P.Ed., after holding the Freeland Barbour research fellowship and winning the Cullen prize. In his younger days he was closely associated with the late Prof. D. Noel Paton and lectured in physiology at the School of Medicine of the Royal Colleges. He was appointed assistant physician to the Edinburgh Royal Infirmary in 1913 and lecturer on clinical medicine in the University in 1914. He collaborated with the late Prof. Lovell Gulland in the production of three editions of a standard book on diseases of the blood, and when the Edinburgh Postgraduate Courses were instituted he lectured on haematology. Dr. Goodall was an early worker in the laboratory of the Royal College of Physicians of Edinburgh and published numerous articles, chiefly on blood diseases and the testing of drugs; he renewed his active interest in the laboratory when he became Vice-President, and again when President, of the College in recent years. During the last war he served in the R.A.M.C. with the rank of major in charge of the medical division of No. 66 General Hospital at Salonika, and while working there contracted an illness from which he never fully recovered. In 1921 he accepted the appointment of physician to the Ministry of Pensions Hospital at Craigleith. He had been a member of the British Medical Association for just on forty years, and at the Annual Meeting in Dublin in 1933 held office as vice-president of the Section of Physiology and Biochemistry.

A colleague in the course of an appreciation printed in the *Scotsman* writes of Dr. Goodall as a shy man, who disliked the ordinary type of medical committee work, where discussions are apt to be prolonged and tedious. He was happiest, in so far as his work was concerned, in teaching and in looking after his patients, to whom he gave of his best from an active brain, wide experience, and a keen clinical sense for the essentials of a case. Those who enjoyed his close friendship were aware of his intense love of his home, his children, and his grandchildren. He was a keen supporter of the Royal Scottish Pipers' Society, and amid many professional duties found time for shooting. He loved the country and all its associations.

WILLIAM KERR RUSSELL, M.D.

William Kerr Russell died on October 4 at the age of 50, after a few weeks' illness. His passing at such a relatively early age is a serious loss to the speciality of physical medicine, which he practised for the greater part of his life.

He was born at Newcastle-upon-Tyne, the son of the late Dr. Frank Russell, a greatly respected practitioner of that city. He was educated at Ackworth School, at Bootham School, York, and the University of Durham College of Medicine, Newcastle. He did extremely well in all examinations, obtaining the coveted Goyder scholarship in clinical medicine and surgery, and first-class honours in the final examination for the degrees of M.B., B.S. In 1921 he received his M.D. for an essay on chronic traumatic osteomyelitis. Qualifying in 1914, he joined the R.A.M.C., S.R., shortly after the outbreak of war, and served in France from early in 1915 till the end of the war. Thereafter he held a surgical appointment in the Military Orthopaedic Hospital, later the Pensions Hospital, at Newcastle.

For several years he was in general practice in his native city, but early in his professional life became interested in electrotherapy, for the technical aspects of which he showed marked aptitude. He was enthusiastic concerning the potentialities of ultra-violet therapy and did pioneer work on that subject. With his wife, Dr. Eleanor Russell, he published in 1925 *Ultra-Violet Radiation and Actinotherapy*, a popular book which ran to three editions. A further book on this subject came from his pen in 1930, and in 1932 he published a monograph on colonic irrigation. He started and superintended a large sun-ray clinic for the benefit of an industrial area of Newcastle. In 1928 he moved to London and entered upon specialist practice in physical medicine. He held the appointments of honorary medical officer to the light department and later the electrical department of the Miller General Hospital, physician in charge of the physiotherapy department, National Temperance Hospital, and assistant in the electrotherapeutic department, Royal Free Hospital. At the Miller Hospital he was co-director of the Almeric Paget School of Physiotherapy from its opening in 1930 until the school was closed in 1936, and for ten years he examined for the Chartered Society of Massage. In 1928 he became assistant editor of the *British Journal of Physical Medicine*, and for a year from 1933 was editor of that journal. He was one of the few people in this country who interested themselves in fever therapy by physical methods, and in 1937 he was official representative of the Ministry of Health at the first International Congress of Fever Therapy in New York. He travelled widely in pursuit of knowledge of his specialty, and was British secretary of the Comité International de la Lumière, and a member of the Ultra-violet Light Committee of the British Standards Institution.

A curiously modest and self-effacing man, Kerr Russell had deep enthusiasm and faith in his work and high ideals. After the outbreak of war, owing to the dislocation of London specialist work, he took the wise decision of transferring to general practice at Ross-on-Wye for the duration of the war. Thus he had a very full and varied life and a wide experience to bring to bear on the problems of special interest to him.

F. J. N.

THOMAS MILL, C.M.G., C.B.E.

M.B., F.R.C.S.Ed.

Tom Mill was the son of a New Zealand shipowner, but himself chose to follow a professional career, and received his medical education at Edinburgh. Immediately after he spent a year as an assistant at Keswick, and there acquired a life-long affection for the place and the people of the Lake District. Then he returned to practise in New Zealand, where his chief preoccupation was with gynaecology. The war of 1914-18 brought him back to England in command of the 2nd New Zealand General Hospital at Walton-on-Thames, where he showed his flair for administration. At the end of the war he studied laryngology and otology in London for a year or two before returning once more to New Zealand, where he held the appointment of aural surgeon at the Christchurch Hospital for ten years. He wrote nothing, but was a wide though fastidious reader, and being, as a New Zealander would be, a man of sterling character and a staunch friend he exercised great professional influence, and held the office of president of the New Zealand Branch of the B.M.A. at a critical period. However, the trend of political events worried him, or at least he thought so. It is probably nearer the truth that a combination of gall-bladder and cardiac disease had begun to undermine his health and made him restless. He resigned at Christchurch and then practised quietly for a time in Jersey, but he had no real ties there, and he left a few days before the Germans took over the island. In the end he returned to Keswick, which he loved so well, and was busily engaged in practice until a coronary occlusion cut him off in a few hours. He will be sadly missed by many besides the New Zealanders whom he served so loyally.

L. C.

Dr. H. S. BURNELL-JONES, D.P.H., died at Worle, Somerset, at the home of his mother on September 17 after a long illness. He had recently been acting as tuberculosis officer for Worcester. Dr. Burnell-Jones received his medical education at Cardiff, Leeds, Bristol, London Hospital, and University College, and had been in practice at West Wickham, Kent, in North London, and, earlier, in Birmingham. He always had leanings towards laboratory work, and was intensely interested in tuberculin treatment, on which subject he had done much research and written several papers. He was at one time a clinical assistant at the Central London Throat, Nose, and Ear Hospital, and after the death of Mr. Juler he ran the throat department of the Croydon General Hospital for some months. He worked for a time in the skin department at the Royal Northern Hospital. Burnell-Jones (writes A. E. S.) was a well-known figure at the meetings of the North London Medical Society. He was a genial personality of spruce appearance, and was an accomplished organist. He leaves a widow, three daughters (one a Bart's nurse, now in the Army), and three sons (two in Canada), all in the Services.

We regret to announce the death at the age of 62 of Dr. ALEXANDER ROBERTSON, medical officer of health for the Burghs of Elgin, Lossiemouth, and Rothes. A graduate of the University of Aberdeen, he took his M.B., Ch.B. degrees in 1902 and his D.P.H. in 1905. Dr. Robertson held an appointment as Government medical officer in Kenya for seven years; on returning to this country he worked for the next four years at the Bermondsey Infirmary in South London as assistant medical officer. Since 1914 he had been engaged in private practice and public health administration at Elgin. At the time of his death he was senior surgeon to Dr. Gray's Hospital. Dr. Robertson was a keen and active member of the British Medical Association from the time of his election in 1920; he served as honorary secretary of the Banffs, Elgin, and Nairn Division for three years and was its chairman in 1931-2, and in 1936 the Northern Counties of Scotland Branch elected him its president. He had been a member of the Scottish Committee of the Association continuously for the past ten years. He was an elder of St. Giles's Church, Elgin, and took a fatherly interest in the local football club, of which he was vice-president and honorary medical adviser.

Dr. HENRY GERVIS, formerly a very well-known Brighton practitioner, died on October 13. Born in London in 1863, he was educated at Mill Hill School and Trinity College, Cambridge, graduating B.A. in the Natural Sciences Tripos of 1884. He then went on to St. Thomas's Hospital and qualified M.R.C.S., L.R.C.P. in 1889, and in the same year took the M.A. and M.B., B.Ch. degrees of Cambridge. He served at St. Thomas's as house-surgeon and resident assistant before starting general practice in Brighton. Dr. Gervis reached high rank in Freemasonry, becoming Provincial Grand Master of Mark Master Masons in Sussex. He took a prominent part in the public life of Brighton and was mayor for one year and afterwards an alderman for eight years; he was also a J.P. for the Borough of Brighton. On the outbreak of the last war he was mobilized on the staff of the 2nd Eastern General Hospital, Brighton, with the rank of Captain R.A.M.C. (T.F.), which he had held since 1908, and in March, 1918, went to serve with the 20th General Hospital at Camiers. On returning to civil life he published some reminiscences of his life in khaki under the title *Arms and the Doctor*. Dr. Gervis was a member of the British Medical Association from 1891 until his retirement from active work five years ago at the age of 73.

Dr. ROBERT THIN (writes Dr. G. M. Greig) was a general practitioner with abilities far beyond the average. In spite of being a busy man with a very large practice he found time for many other activities in connexion with the profession and the Church, and he wrote papers on various subjects. His great personal popularity, his capabilities, and the esteem in which he was held were recognized by his election to the Presidency of the Royal College of Physicians of Edinburgh, and by the conferring on him by the University of Edinburgh of the honorary degree of LL.D. But it is as the family doctor and friend that those of us who were his patients will think of him and remember him. At one period the work he did must have seemed almost too much for even his great capacity, but he never appeared to

be hurried. His examination of the patient was always systematic and thorough, and his visits left his patients cheered and full of confidence. No man was ever more kind and sympathetic. We remember these words of Savonarola: "The physician that bringeth love and charity to the sick, if he be good and kind and learned and skilful, none can be better than he." And we know that no man ever more deserved them than Dr. Thin.

The Services

CASUALTIES IN THE MEDICAL SERVICES

ROYAL NAVY

Temporary Surgeon Lieut. ARTHUR CHARLES SHELFORD, R.N.V.R., who was announced as "Missing" in the *Journal* of September 21, 1940 (p. 402), is now reported to have died as a prisoner of war and to have been buried on Pellworm Island on September 26, 1940. He was born at Alnwick in 1914 and began his medical studies at the University of Edinburgh in 1932, graduating M.B., Ch.B. in 1937. He had held the posts of house-physician and house-surgeon at Sunderland Royal Infirmary. Soon after the outbreak of war he was granted a temporary commission as surgeon lieutenant in the R.N.V.R., and early in 1940 was posted to H.M.S. *Express* and assisted in the Dunkirk evacuation. He joined the British Medical Association soon after qualification.

ROYAL ARMY MEDICAL CORPS

Prisoner of War

Lieut. John Campbell.

DEATHS IN THE SERVICES

Colonel LEONARD WOOD, late R.A.M.C. (ret.), died at Westbury, Wiltshire, on September 27, aged 67. He was born on July 20, 1874, was educated at Mason College, Birmingham, and took the M.R.C.S., L.R.C.P. in 1898. After filling the house posts at the General Hospital, Birmingham, he entered the R.A.M.C. as lieutenant in 1899, becoming full colonel in 1926. In 1910-11 he served as adjutant of Territorial Army units. He served throughout the South African War of 1899-1902, when he took part in the relief of Kimberley and in operations in the Orange Free State, receiving the Queen's medal with three clasps and the King's medal with two clasps. In the war of 1914-18 he served as a D.D.M.S. and was mentioned in dispatches in 1917. After retirement he was employed at Trowbridge. He leaves a widow.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The President of the Royal College of Surgeons, Sir Alfred Webb-Johnson, gave a luncheon party on October 9 at Claridge's. The company included members of the Council and officers of the College; the Presidents of the Royal College of Physicians and the Royal College of Obstetricians and Gynaecologists; the Medical Directors-General of the Services; and Viscount Dawson of Penn and Lord Horder. Among the many other distinguished guests were the President of the Czechoslovak Republic, the Soviet Ambassador, the Egyptian Ambassador, and the Czechoslovak Minister of the Interior and Education; the First Lord of the Admiralty and the Minister of Health; the High Commissioners for Canada, Australia, New Zealand, and South Africa; Captain Crookshank, M.P., Major Lloyd George, M.P., and Colonel the Hon. John Astor, M.P.; Brigadier R. Luton, D.M.S., Canadian Forces, Wing Commander A. R. Tilley, R.C.A.F., Lieut.-Colonel J. H. Anderson, R.A.A.M.C., Squadron Leader E. H. Anderson, R.A.A.F., Captain W. M. Anderson, U.S. Navy, and Colonel Paul R. Hawley, U.S. Army.

In his speech Sir Alfred gave a special welcome to the President of the Czechoslovak Republic and said that the Royal Colleges were proud to have the privilege of conducting examinations for the medical degrees of the University of Prague. He spoke of the admiration felt by all present for the gallant Soviet Army, and their sympathy for the sacrifices and sufferings of the Russian people; the College was grateful for the Ambassador's personal support in its endeavours to establish closer liaison between the medical services of the two countries. The Egyptian Ambassador was an old friend of the College, for it had had close associations

with the Egyptian University for many years, and its Rector was an Honorary Fellow. The presence of the High Commissioners for the four Dominions was a reminder that our Royal Colleges had an imperial as well as a national importance and significance. Welcoming Admiral Dudley, General Hood, and Air Marshal Sir Harold Whittingham he expressed the hope that one outcome of this war would be that the heads of the Ministries of Defence would realize that their Medical Directors-General should have a place at the highest Council table; the war had made it clear that in tactics as well as strategy nearly every phase had its medical aspect. After a word of special greeting to medical representatives in this country of the Dominion Forces and of the United States, and to the Hunterian Trustees who attended the luncheon, the President made reference to the loss the College had sustained by enemy action. Though it might seem trivial compared with the losses and sacrifices of our Allies, yet it was a calamity of the first order—a loss to science. The Museum was unique in the world. "Our loss is serious, but in the great event it is but an incident and one which we may consider it a privilege to repair. We have a summons to a high duty, a mighty and noble task, in which we are encouraged by offers of help from all parts of the world. What high destiny to be on the Council now, when every step we take is history! It may be that this disaster will pave the way to the finest hour in the history of our College. The first step towards repair was taken with dramatic promptitude, for at the very first regular meeting of the Council after the disaster we received an inspiring message from the Bernhard Baron Trustees offering a gift of £40,000 to endow a research professorship at the College, so that, in our preoccupation with the restoration of the Museum, research should not suffer. . . . We have Hunter's plan and the inspiration of his example. On these foundations we must rebuild the superstructure—not perhaps exactly as it was, but as he would have built it had he been equipped with all the aids we have to-day."

The First Lord of the Admiralty and the Minister of Health replied to the President's toast: "To the Hunterian Tradition; to the restoration of our Museum; to the success of our Allied Arms; and to the attainment of Victory, for it is only through Victory that our goal can be won."

Council Meeting

At a quarterly meeting of the Council of the Royal College of Surgeons of England, held on October 9, with Sir Alfred Webb-Johnson, President, in the chair, Mr. D. L. Kerr was admitted as a Macloghlin Scholar.

Prof. John Beattie was appointed Bernhard Baron Research Professor.

It was decided not to fill the post of Conservator of the Museum at present. Prof. A. J. E. Cave, Assistant Conservator, will continue in charge for the time being.

The following awards were reported: A Proffit Studentship to Dr. J. Clark Davidson and a Mackenzie Mackinnon Research Fellowship to Dr. Geoffrey Bourne.

It was decided to recognize the posts of resident surgical officer and one house-surgeon at the Kent and Sussex Hospital, and the house-surgeon at the Walsall General Hospital, for the six months surgical practice required of candidates for the Final Fellowship examination.

A Diploma of Fellowship was granted to Peter Smith, M.B., B.S. Diplomas of Membership were granted to F. X. Darne, J. D. C. Gowans, D. K. Sambrook, A. L. H. Smith, and Glenys J. Wade.

Diplomas in Child Health were granted, jointly with the Royal College of Physicians of London, to the following eleven candidates: A. W. Abramson, W. W. Burnett, Winifred McK. Davidson, W. G. Daynes, Mabel A. Henderson, S. L. Mohan, D. Morris, Lorna C. Petersen, G. Prasad, I. D. Riley, Margaret M. Strange.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council, held on October 10, Prof. G. A. Clark was reappointed representative of the University on the General Medical Council, and Mrs. Margaret G. Happey, M.B., Ch.B., was appointed assistant bacteriologist.

The Council received the resignation of Dr. R. W. John of the posts of research assistant and honorary demonstrator in pathology with regret, and accorded its thanks to him for his services to the university.

The Faculty of Medicine reported that the success which attended two short courses in industrial medicine, held during

the summer vacation, had demonstrated the growing realization of the importance of reducing health hazards among industrial workers. Lectures and demonstrations were given by some of H.M. Medical Inspectors of Factories, by members of the teaching staff of the Medical School, and by the staff of the Mines Research Board, and visits were paid to the works of Messrs. Edgar Allen and Co., Ltd., and Messrs. Hadfields, Ltd. The Faculty was glad to have fostered the spirit of co-operation between industry and medicine, and hoped to have further opportunities of doing so in the future.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh, held on October 15, with Dr. H. M. Traquair, President, in the chair, the following who passed the requisite examinations were admitted Fellows:

W. V. Beach, D. W. Bracey, M. S. Campbell, I. Chand, C. D. Coode, H. K. Dastur, H. De, J. C. Dick, H. L. Duncan, M. Gamal el-Din, T. Gibson, W. H. Kirkaldy-Willis, M. A. M. Labib, H. A. McDonald, W. C. McGuire, G. MacKay, J. W. Morgenthal, J. M. H. Ross.

At the annual meeting of the College, held on October 15, the following officers were elected for the ensuing year:

President, Mr. J. W. Struthers. Vice-President, Dr. H. M. Traquair. Secretary and Treasurer, Mr. K. Paterson Brown. Representative on the General Medical Council, Mr. Alex. Miles. Convener of Museum Committee, Mr. W. Quarry Wood. Librarian, Dr. Douglas Guthrie.

Medical Notes in Parliament

Psychiatry in the Army

On October 7 the Parliamentary Medical Committee, with Sir Francis Fremantle in the chair, was addressed by Colonel J. R. Rees, Director of Army Psychiatry and head of the Tavistock Clinic. He gave an account of the psychiatric work now done in each Army Command and showed that the classification of difficult cases had a good effect on Army morale. These cases seemed more prone to appear in military service than under civil conditions.

Return of Tuberculous Soldiers from South Africa

Captain MARGESSON denied on October 9 that any special orders had been issued by his Department for forty military tuberculosis cases in the Addington Hospital, Natal, and 120 similar cases at Oribi, to be returned to this country. He said there were general instructions regarding the return to this country from South Africa of soldiers suffering from tuberculosis. On arrival in this country soldiers suffering from tuberculosis were sent to a military hospital, where they received treatment as necessary until handed over to the care of the local health authority.

Medical Services of Soldiers' Dependants

On October 14 Dr. HADEN GUEST asked the Secretary of State for War why the privilege of medical and dental treatment accorded to the families of regular soldiers now serving, and to those of reservists called up for service, was not given to the families of the soldiers enlisted or called up since the beginning of the war. Captain MARGESSON replied that the extension to the families of soldiers enlisted since the war of the facilities for medical and dental treatment at present enjoyed by the families of regular soldiers or reservists now serving would involve an enormous increase in the numbers of Army medical and dental officers, which could only be effected at the expense of the civil medical services. Moreover, the families of regular soldiers were not eligible for medical attendance in their homes unless they lived within a mile of certain fixed points, and if the concession were extended to the families of wartime soldiers its value would therefore vary according to the family's domicile.

Scotland's Post-war Hospital Policy

On October 14 Mr. MCNEIL asked the Secretary of State for Scotland if he could give further details of the Government's post-war hospital policy for Scotland in relation to voluntary and emergency hospitals. Mr. JOHNSTON said that he proposed

to have consultations at an early date with the various organizations, including the associations of local authorities, concerned with hospital services in Scotland. In the meantime he could not add to the statement made in the House of Commons by the Minister of Health on October 9.

Increase of Tuberculosis

Mr. ERNEST BROWN announced on October 16 that, on the basis of provisional mortality figures for 1939 and 1940, the percentage increase in pulmonary tuberculosis in England and Wales for the population as a whole was 9.7% higher in 1940 than in 1939. The highest rate of increase was 15% among women between the ages of 15 and 25. In the first quarter of 1941 there had, however, been a reduction of 7% for the population as a whole, and of 4% for women between the ages of 15 and 25. With the co-operation of the Medical Research Council he had arranged an expert investigation into the possible causes of increase. Everything possible was being done to maintain the tuberculosis service.

Alien Doctors' Employment

In an answer on October 16 to Sir Henry Morris Jones Mr. BROWN announced that the number of alien doctors registered under the Medical Register (Temporary Registration) Orders, 1941, by virtue of employment in approved services, was 470, apart from American doctors dealt with under the Order of 1940. Of the total of 470, 385 were employed in hospitals, 33 in public health appointments, and 52 as ship surgeons or in other miscellaneous posts. In addition, 24 received commissions in our Services, apart from those serving in Allied Forces. He recalled that the Order made on September 23 last provided an avenue of service in general practice by enabling alien doctors to be registered by virtue of employment as assistants to doctors already on the permanent Medical Register. The number of doctors still available was approximately 500, including those who had only recently become eligible for registration under the amended Defence Regulation 32B.

First-aid Equipment of Home Guard.—Mr. GROVES alleged on October 2 that the only dressing suitable for dealing with burns which had been issued to the Home Guard was tannic acid jelly, and that this jelly was by medical men considered to be more dangerous than useful in cases of burning of the hands or face or any exposed part of the body. Captain MARGESSON said he was looking into this question. Answering further questions he said all first-aid dressings issued for immediate use at Home Guard posts were impregnated with an antiseptic. Asked whether he knew that wooden splints issued to the Home Guard were so short that they would be useless for the proper control of a fractured leg, Captain MARGESSON replied on October 2 that arrangements were in hand for provision of suitable splints at regimental aid posts.

Hospital Domestic Staffs.—In a reply on October 9 to Mrs. Rathbone, Mr. BROWN said he had for some time been concerned because many voluntary hospitals were seriously hampered owing to lack of ancillary staff such as stokers, porters, and wardmaids. He had recently discussed these difficulties with representatives of voluntary hospitals. Domestic work in hospitals was recognized as one of the services of most urgent national importance for which recruitment was to be carried out by the Minister of Labour. He had issued a poster for circulation to hospitals to make this important clear to those already employed in hospitals.

Special Examinations for Employment Exchanges.—On October 11 Mr. GROVES asked the Minister of Labour if he was aware that doctors were being required by certain employment exchanges to undertake urine tests over a period; if such examination was part of the ordinary services of the doctor; and if a special fee was to be paid. Mr. BEVIN: I understand that such action was taken in one district at the request of the medical board. The action was unauthorized, and steps have been taken to prevent its recurrence.

Notes in Brief

Mr. Ernest Brown hopes to issue within three or four weeks report for 1940 of the Chief Inspector of Factories.

In accordance with the general decision to suspend the inter-departmental reports not immediately essential to the war effort, regular series of reports of the Ministry of Health and of the Medical Officer will be suspended until after the war. Mr. E. Brown hopes, however, that a summary will be ready within the next two months.

Publication of the annual reports of the Chief Medical Officer of the Board of Education will be deferred till after the war.

No. 40

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 4.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1941					1940 (Corresponding Week)

Annual rate per 1,000 persons living
Stillbirths	204	16	33	—	—	206	19	48	—	—
Rate per 1,000 total births (including stillborn)

* Includes paratyphoid A and B for Northern Ireland.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Owing to evacuation schemes and other movements of population birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of the Table

The feature of this week's returns for England and Wales is the large increase in the cases of pneumonia—144—although a sharp increase during this period of the year is not an unusual experience. The notifications of the common infectious diseases—scarlet fever, whooping-cough, diphtheria, and measles—were all below the totals of the preceding week. No marked deviation in the geographical distribution of scarlet fever occurred, but the fall in the incidence of diphtheria was mainly due to the decrease in the Northern Counties, where the incidence had been rising lately. The large increase in the notifications of scarlet fever reported in Scotland was due to a general rise in the incidence throughout the country.

Fewer cases of paratyphoid were recorded in England and Wales. Six cases of typhoid were notified in Kent (Orpington U.D.).

Dysentery

Nineteen cases in excess of the previous total occurred in England and Wales. Small increases were returned by ten counties; 17 cases were notified in Bristol C.B. A serious increase was recorded in Scotland—175 cases compared with 71 in the previous week: an outbreak in the county of Lanark. 103 cases, was responsible for this.

Cerebrospinal Fever

The only changes of any note in the distribution of the notifications of this disease in England and Wales were those shown by Durham and Lancaster. Durham had 9 cases (Sunderland C.B. 6), compared with 3 in the preceding week, and Lancaster had 22 cases, against 10 in the previous week. In Lancaster the cases were scattered throughout the county, and with the exception of Manchester C.B., 7, no administrative area notified more than 2. A small rise (4 cases) occurred in Scotland, but with the exception of the city of Glasgow, 13, no district had more than 2 notifications.

Poliomyelitis

The 31 cases recorded in England and Wales were 7 below the total of the preceding week. For the second week in succession 5 cases were notified in Berkshire, in four administrative areas. Three further cases were reported from Oxford C.B. The 4 cases reported in Middlesex were from three separated districts. Two cases were notified in Surrey (Caterham and Wallingham) and Lancaster (Manchester C.B.). In Scotland an outbreak in Dumfries County accounted for 4 of the 6 cases notified. In Eire 2 cases occurred in Dublin and 3 in the urban district of Ballina, County Mayo. The 2 cases notified in Northern Ireland were from the rural district of Ballymoney.

Quarterly Return of the Registrar-General for Scotland

The vital statistics for Scotland for the second quarter of 1941 show some considerable variations from the average trend. The birth rate of 18.3 per 1,000 live births was the lowest ever recorded in a second quarter. The infant mortality, 84 per 1,000 live births, was 17 above the average for the quarter, and the maternal mortality, 5.3 per 1,000 live births, was 20% in excess. The death rate was 15.4 per 1,000, and when adjusted for the effect of the withdrawal of a large number of males for active service still remained 2.0 above the average for the second quarters of the five preceding years. The excess of deaths was most apparent among infants and at the highest ages. Deaths from tuberculosis, cerebral haemorrhage and allied conditions, and heart disease were considerably above the average. The excessive infant mortality was due to marked increases in deaths from diseases of the respiratory system and whooping-cough (301 deaths against an average of 133). Deaths from premature births also showed a considerable rise. Six hundred and fifty-three deaths were attributed to the principal epidemic diseases, and of these 94% were due to whooping-cough, diphtheria, influenza, and cerebrospinal fever, which had 269, 117, 117, and 113 deaths respectively.

Returns for the Week Ending October 11

The notifications of infectious diseases in England and Wales during the week included scarlet fever 1,336, whooping-cough 1,970, diphtheria 1,034, measles 787, cerebrospinal fever 110, poliomyelitis 38, dysentery 207, paratyphoid 64, and typhoid 23.

Medical News

A Chadwick Public Lecture on the cleansing of towns and cities will be given by Mr. J. C. Dawes of the Ministry of Health, at the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.1, on Tuesday, October 28, at 2.30 p.m.

Dr. John Parkinson will deliver a lecture on "Cardiac Diagnosis in Wartime" at the Weston Hotel, Bath, on Thursday, October 30, at 5.30 p.m. All Service medical officers and civilian practitioners will be welcome.

A meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health was held at Tavistock House South on October 4, the president of the group, Dr. E. Virginia Saunders Jacobs, being in the chair. Dr. Wilfrid Sheldon, physician to out-patients, Hospital for Sick Children, Great Ormond Street, opened a discussion of much interest on the effect of war conditions on young children. All speakers were unanimous in reporting the absence of deficiency diseases (rickets and scurvy), and the general evidence went to show that the health of young children had improved rather than deteriorated since the onset of war—a profoundly satisfactory result. Tributes were paid to the Government's policy in inaugurating and maintaining the national milk scheme and to the work of the welfare authorities in supplying extra vitamin preparations. The value of the national dried milk for infants was emphasized. While the Government's evacuation scheme had proved of great benefit to the health of children as a whole, Dr. Sheldon raised an important point in drawing attention to the danger of children being billeted in any house where there was a case of open tuberculosis and to the need for liaison between billeting officers and the health departments.

The Polar Medal (bronze) has been awarded to Dr. Edward Hillis Marshall, D.S.O., for good services between the years 1925 and 1939 in the Royal Research Ships *Discovery II* and *William Scoresby*.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Airloggy Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Function of the Vocal Cords

Dr. GRACE McLINTOCK (Glasgow) writes in reply to the query by Dr. John Donald (October 4, p. 496): There is a paragraph in *The Story of Medicine*, by Victor Robinson, on page 132, where Galen's descriptive passage is produced.

R. S. S. writes: In reply to Dr. John Donald, the best edition of Galen's *De Usu Partium* is Kühn's, published by Teubner, Leipzig, in 1893. Dr. Jonathan Wright's *History of Laryngology and Rhinology* (Philadelphia, Lea and Febiger, 1914) will tell him a great deal about Galen's observations on the larynx, but not the point about which he asks. Galen described accurately the cartilages of the larynx, six pairs of intralaryngeal muscles, the laryngeal ventricles, and the innervation of the larynx, but is somewhat confused and long-winded about the production of the voice. He understood, however, that the voice was produced at the glottis. "As the pipe would be useless without the reed, so voice could not be formed unless the passage is narrowed. . . . In order

that the animal may emit voice it requires no doubt the movement of the breath, but none the less the narrowing of the channel of the larynx, not a simple narrowing, but one which can by degrees be constricted and by degrees relaxed" (*De Usu Partium*, Book VII, chapter 17). Galen gives himself credit for many anatomical discoveries, such as the recurrent laryngeal nerves and the laryngeal ventricles, but he was a collector of and commentator on the discoveries of his predecessors, as well as being one of the few experimental physiologists.

Benzyl Benzoate Therapy

Dr. SIDNEY LOCKET (Plymouth) writes: As benzol and benzoic acid do frequently cause hypoplasia and aplasia of the bone marrow and aplastic types of anaemia, might not the frequent use of benzyl benzoate for scabies have a similar effect on sensitive or even normal people?

Income Tax

Appointment under Emergency Medical Service

"MIDLAND": An inspector of taxes claims to include the value of board and lodging supplied, on the ground that if it were not supplied then £100 per annum would be received in cash and would admittedly be assessable.

** Income tax must be assessed according to the facts of the particular case, and arguments that if those facts were other than they are then liability would be clear are irrelevant. In the case of *Cordy v. Gordon* the court drew a distinction between (a) an agreement under which the employer paid £x and provided board and lodging worth £y, and (b) an agreement under which £x+£y was payable less a deduction of £y for board and lodging provided. The liability is on £x in the former case and on £x+£y in the latter case, and unless, on the terms of the agreement, express or clearly implied, the particular case in question falls within the former type the inspector's view appears to be incorrect. If he declines to reconsider it we suggest that the facts be reported to the Board of Inland Revenue and their ruling on the question sought. We cannot see that liability to frequent removal can affect any question of liability to assessment in respect of board, etc., supplied in kind, although it might negative the Revenue contention that a cash allowance for board, etc., was assessable.

LETTERS, NOTES, ETC.

Treatment of Incontinence in Children over Four

Dr. CHARLES PEDDIE (Chorley) writes: Might I suggest a much simpler method of curing enuresis in children than that of Dr. J. Hartsilver (October 4, p. 496). I use light hypnosis and, in this condition, suggest that when the bladder requires to be emptied, no matter how deeply asleep they are, they will waken up, get out of bed, sit on the chamber, get back into bed, and sleep until the usual time for getting up. It is over six years ago that I had my last case—a girl of 16 who used to wake up wet to the armpits. The family consisted of herself and brother, and the mother lavished all her love on the boy, and so the bed-wetting started through jealousy and continued up to my using this method. Explanation was given of the origin of her trouble. To-day she is on war work and doing it well. Children are easy subjects in whom to induce light hypnosis.

This Certification Business

Mr. E. WATSON-WILLIAMS (Bristol) writes: The question of medical certificates for glucose seems to need some attention. Quite a number of patients seem to think that if they want to supplement their sugar ration it is the doctor's duty to help them. About a fortnight ago I attended a (gratis) patient for epistaxis. To-day I was asked to call and see her (my diagnosis had been menorrhagia plus complete lack of exercise). I found her taking tea and toast, buns, and having declined an invitation to join her, the following dialogue took place. Patient: "I want you to give me a certificate so that I may get some glucose." Reply: "But why do you need glucose?" Patient: "I think it would do me good. I feel dreadfully tired. Miss Q. and Katie R. and Sally S. take it and find it is so helpful." Reply: "Shall I order you some malt extract?" Patient: "Oh no! That is so fattening." Reply: "But a spoonful of malt extract will have the same effect as you took glucose." Patient: "Well, why can't you give me a certificate that I need glucose?" You haven't examined me, so you can't possibly tell that I don't need it."

Corrigendum

In Dr. Leslie Ballon's letter on "Perfect Sight Without Glasses" on page 562 of our issue for October 18, the word "gently," in lines from the foot of column 1, should have read "generally." "a line of treatment delivered generally may be harmful."

THE CORRELATION OF PATHOLOGY, PHYSICAL SIGNS, AND X-RAY APPEARANCES IN THE DEVELOPMENT OF LUNG CAVITATION*

BY

R. R. TRAIL, M.C., M.A., M.D., F.R.C.P.

Physician, Royal Chest Hospital, London; Physician to Surgical Unit, Papworth; Wing Commander, R.A.F.V.R.

The correlation of pathological findings with physical and radiological signs is an unfailing source of interest to the diagnostician. In diseases of the chest such a study is a fascinating game. It is still a game, in the nature of a jigsaw puzzle, in that the answer we continue to seek assiduously in most of the problems set is the individual living pathology, the pathogenesis at the moment of diagnosis, which shall act as the basis of that wider problem of individual treatment, ever the ultimate aim and true reward of the happy physician. Not every player plays the game with the same pieces. Some claim ability to find the answer with a limited number; some even despise certain sets of pieces.

Controversial articles on the value of mass radiography recently appearing in the medical press serve to illustrate this point. Certain writers have professed to be independent of x-ray aids in the diagnosis of tuberculosis; they say that to them clinical history and stethoscopic signs are all-sufficient. Some have gone to the other extreme and have relegated the stethoscope to the scrap-heap. Both classes may, as individuals, be entirely truthful in their statements, the first having ears to hear and the second eyes to see. We do well, however, to ignore deaf advocates of perpetual ear stops, however well they can see, and preachers of permanent blinkers, however well they can hear. The "useless" club in our golf outfit is too often the one we have never learnt to use. The truth is, we still require every possible aid—pathological, radiological, and stethoscopic—in the diagnosis of chest disease if we would belong to the class of the happy physician "who stops, and who looks, and who listens."

Let us consider how these principles affect the discovery of cavitation, throughout its development, in bronchiectasis, abscess of lung, and tuberculosis.

Bronchiectasis

We will leave aside the much-discussed subject of congenital bronchiectasis and confine ourselves to the disease in its acquired form. Even here there is controversy on the intrabronchial or extrabronchial origin, but it is generally accepted that the first recognizable pathological change is dilatation of the bronchus, due to obstruction plus infection, and that this dilatation is the first step in the production of the bronchiectatic abscess cavity.

In children the process is usually very acute, taking the form of ulcerative bronchitis, which breaks down the bronchial wall and invades the lung substance so rapidly that all the clinical and radiological findings of an advanced stage of adolescent and adult forms of the disease present almost from the first symptomatic evidences.

From adolescence onwards the progress of the disease is generally much slower. Here chronic upper respiratory tract infections and chronic bronchitis are early secondary invaders of the damaged and weakened bronchi, and cause a loss of muscle tone that in its turn produces further dilatation. The normal action of respiratory widening by comparative negative intrathoracic pressure, exerted by the pleural vacuum, is not now followed by normal contraction of undamaged elastic tissue, and this vicious circle is continued by the resultant accumulation of debris in the lumen, interfering by its dead weight with the natural sweeping movements of the cilia.

Microscopical examination shows affected bronchi to be chronically inflamed and slowly breaking down and atrophying. In some parts only the epithelium will be affected; in others muscle and elastic tissue are fast disappearing: while in an advanced area every element of the bronchial wall is mixed beyond recognition into a dense fibrous mass, and the ciliated columnar epithelium is beginning to show squamous-cell infiltration. Surrounding areas of the lung show compensatory emphysema.

At this stage the physical and x-ray findings are in most cases bilateral and basal. The heart is central; there is no mediastinal displacement; and clubbing of the fingers, if recognizably present, is still at the first stage. This consists of an excess of tissue at the root of the nails—cyanotic, and with an unnatural shine as from continual polishing. The movement of the chest is heaving in the lower zones rather than lateral, owing to compensatory emphysema. The note to light percussion is impaired, but the overlying emphysema may very easily produce a deceptive tympany. In most cases, as there is still some airway in the bronchi, rhonchi and sibili are heard through the whole inspiratory phase: but they are most insistent in the first half of the phase, and return equally loudly in the middle and last phases of expiration. If such added sounds remain after cough they are lessened in intensity and practically confined to the early phase of inspiration. In addition, there are heard throughout the whole of inspiration, both on ordinary breathing and after cough, fine to coarse sounds of a dry character. The characteristic appearance of increased striation on the film and the microscopical finding of increased deposition of connective tissue in and around the bronchi and their associated alveoli have taught us to recognize these as the stethoscopic finding of established fibrosis.

The x-ray film taken at this stage shows heavy, rather fluffy linear shadows towards both bases, irregular in their loss of translucency, but more or less faithful to the normal branchings of the larger bronchial bundles. We are viewing the increased blood supply of chronically inflamed bronchi, and occasionally slight invasions of lung tissue through penetrated bronchial walls.

* Read before the Ely Medical Society of the R.A.F. on June 8, 1941.

The introduction of lipiodol would show enlarged bronchi, slowly increasing in width from the upper border of the affected area downwards towards the bases, occasionally pulled into small nodular sacculations, and now and again without true definition in the shadows of their edges.

The further stages, so well demonstrated in children, constitute a picture of rapid deterioration. Increased inflammation produces complete destruction of the elastic and muscle fibres; resultant debris brings occlusion of the lumen; the cilia give up the unequal struggle, and their consequent paresis is followed by organization, shown in the replacement of their columnar by squamous-cell epithelium. Endarteritis of the vessels in the walls brings increased fibrosis; areas of atelectasis in the alveoli of the neighbouring bronchioles add to the negative intrathoracic pressure already pulling the dilated lumen into sacculi, until finally there is complete destruction of all elements, including the cartilage, and perforation brings further sepsis to surrounding parenchyma.

The x-ray picture changes with these developments. Linear densities previously noted become more irregular and extensive, and fibrosis is demonstrated by the shift of the heart and mediastinum to the affected or more affected side. Septic extensions through the bronchi to lung tissue are seen as ill-defined areas of loss of translucency, like blobs of cotton-wool, around and intimately mixed with the shadows of chronically inflamed and dilated bronchi. These, at first small and more or less discrete in the acute state, later become confluent, and are often entirely similar to the shadow now called that of pneumonitis; they have, however, a distinctive and diagnostic difference in that the accompanying fibrosis produces mediastinal shift. Such shadows come and go with the onset of and recovery from the well-known exacerbations of the established disease. But temporary recovery only adds to the vicious circle of dilatation of the bronchi as new areas of atelectasis repeat the previous process, so that the basic and diagnostic appearances of marked peribronchial vascularity are still heavier, more grossly contorted, and less and less associated with the linear distribution of normal bronchi.

Examination with lipiodol will show exaggerations of the anomalies previously noted on its introduction. Enlargement is much more pronounced, the edges of the bronchi will be more confused and nodular; some will show nothing comparable with normal outlines, but be replaced by gross sacculations, while still others will be completely indistinguishable and lost in a ragged cavity invading surrounding parenchyma to greater or lesser degree.

Physical signs have also altered. The mediastinum has moved to the affected or more affected side. Such shift is most easily demonstrated by the "sterno-mastoid sign." This consists in gentle palpation of the band of the sterno-mastoid towards its origin at the inner end of the clavicle while the patient is lying or sitting in a relaxed position with the head central to the thorax. On that side to which the mediastinum is either pulled or pushed there will be found marked tension. The scaleni on the same side of the neck may be similarly affected. Simple scoliosis can produce such a sign in minor degree, but can be excluded very easily by chest inspection alone.

Developed osteo-arthritis is now an evident sign. This is "septic" in type: the whole terminal phalanx is involved, enlarged in all diameters, gross, clumsy, and "drumstick" in appearance. Such clubbing is entirely different from the usual finding in tuberculosis, where the enlargement is "dorsal-palmar" in type, and tends to give a more claw-like, tapered, and refined look to the fingers.

Marked lack of movement and dullness are present over the affected areas. Added sounds take on a new and distinctive character. Coarse rhonchi may be heard between exacerbations, as there are areas of incomplete blockage of the lumen; but the most diagnostic signs in such conditions are rales, exceedingly coarse and metallic, best heard in the first phase of inspiration, and remaining post-tussive. They tail off in the second half of inspiration to those already described as evidence of fibrosis, and tell us our patient has reached the stage of sacculation and abscess-cavity formation. Destruction of all elements of the bronchial wall is active and progressive.

During exacerbations the areas with surrounding pneumonitis may be quite silent owing to complete blockage of the lumen and the filling of communicating lobules with pneumonic exudate, but examination repeated after a period of rest in bed will show further increase in numbers and intensity of the characteristic metallic rales, which encroach more and more into the middle phase of inspiration, showing that the patient has now developed lung abscess of bronchiectatic origin.

Lung Abscess

The cavitation of lung abscess which is not bronchiectatic in origin is entirely different in physical and radiological signs throughout its development, although its pathology is rather similar in its main features. We have seen that in bronchiectatic cavity formation the primary process may be followed from an intrabronchial origin and that the abscess is an involvement of parenchyma by extension. Such an abscess cavity is met with in overflow, by proximity plus pressure, in cases of empyema, and is common in the interlobar type. It is similarly found after aspiration of foreign bodies and septic material into the bronchi—for example, after operations on the upper respiratory tract.

We will not deal here with multiple small abscess formation due to dissemination of septic emboli through the blood stream, where the breaking down is an extension of connective-tissue destruction, but will confine ourselves to that type of abscess which has its beginnings in the alveolar spaces and follows bronchopneumonia and, more rarely, pneumonia as the primary disease. We find that the branches of the more vertical right lower bronchi are more frequently involved than the left in bronchopneumonic cases: for the same reason the upper lobes are more rarely affected than the lower. The site of the lesion is far more often peripheral than central. The majority of the abscesses are superficial, and so immediately under the pleura that it is affected from the onset. At an early stage they are not easily determined in outline post mortem, being merely mushy gangrenous-looking areas in the middle of bunches of alveoli occluded by typical pneumonic exudate. There is, however, a very distinct change in the film associated with the causative disease. If this has been pneumonia, the loss of translucency, previously equal from periphery to heart shadow at any one level throughout its extent, becomes greater in the abscess area, and comparatively less to entire absence, in other areas of the affected lobe. The denser area is generally in the outer zone of the lung field. There is no shift of the trachea or mediastinum to the diseased side.

If the previous condition has been bronchopneumonia the alteration in shadow is just as dramatic. In place of scattered areas of loss of translucency, never confluent and yet never entirely separated by normal translucent areas, and generally much more evident over one lower zone than the other, there appears the shadow described above. This is confluent, ill defined in its edges, and heaviest in its central zone.

To physical examination there is definite lack of movement of the affected side and a fairly limited impairment of note. The diagnostic stethoscopic sign is a coarse pleural rub, usually far more extensive than the area of dullness, and out of all proportion to symptoms; indeed, it may be entirely painless. Such a finding over the right upper lobe, especially if it be post-operative to upper sinus infection and anterior and below the clavicle, is almost by itself diagnostic of abscess formation. When actual cavitation occurs the pleural rub either becomes very localized and annular in distribution to the underlying lung lesion, or disappears entirely, as the pleura has become adherent and thickened in its layers. But a new and equally diagnostic stethoscopic sign appears.

In pneumonic cases, in place of the redux crepitations of reopening alveoli, coarse metallic rales of the character already described in bronchiectatic abscess are heard, this time most insistent in the mid-phase of inspiration. They are, so far as their appearance in inspiration is concerned, the signs we heard in the last stages of abscess formation in bronchiectasis, where the lung involvement was secondary to bronchial sacculatation: there they were a continuation to the mid-phase from the first phase of inspiration: now they begin in the mid-phase as lung involvement by sepsis precedes bronchial involvement. Accompanying them throughout inspiration there may be high-pitched sibili and coarse rhonchi, of the type commonly found in partial blockage of the bronchi. Where bronchopneumonia has been the preceding disease these metallic rales replace the moist rales, of definitely less intensity, heard in the same phase of inspiration in all ordinary uncomplicated cases.

There is still at this stage no shift of the mediastinum to either physical or radiological findings, but the latter change within the area of the actual lesion. Towards the centre of the dense area a translucency becomes apparent, either ill defined or with a linear edging only, oval or rounded in shape. A fluid level may appear, but is unusual at this stage. Its outline is no more marked by viewing the film at the distance of some six feet than it is on close inspection, nor does any change appear at differing distances in the surrounding area of loss of translucency. In both such features, as we shall see later, the film differs considerably from that of fibro-caseous tuberculosis with cavitation. The reason for this we can find by examination of the cavity at such a stage post mortem. The wall is not fibrotic but ill defined and ragged, and is heavily infiltrated with large mononuclear phagocytes and polymorphs. The surrounding alveoli are filled with typical pneumonic exudate. Should such a cavity not be evacuated further changes will appear. Generally within three to four weeks of its first formation dense fibrous tissue appears in its wall, shutting it off from surrounding lung. Similarly, organization of their pneumonic exudate is followed by induration of surrounding alveoli. Bronchi become infected and bronchiectasis supervenes; we are witnessing the reverse process, albeit in a restricted area, which we followed in the formation of abscess cavity in primary bronchiectasis.

Film now shows a well-defined cavity wall, rounder and smoother in outline than the chronic tuberculous cavity, and more apt to contain a fluid level. Further in comparison with such a cavity, it changes more suddenly from its well-defined inner wall to a generalized loss of translucency in surrounding lung tissue, and therefore still alters but little by distant viewing as against close inspection. Pathology tells us why: induration and organization are confined in lung abscess to alveoli close to the circumscribed lesion, but in fibro-caseous tuberculosis acinar collapse and fibrosis are widespread in comparison, and generally

scattered throughout at least the major part of the diseased lobe in which the cavity develops.

Commencing mediastinal shift, now evident on the film, can be discovered by physical examination, and is due to the increasing fibrosis, which adds its stethoscopic signs, already described, to those of the still more insistent metallic rales. They are a definite danger signal; they show that the basis is laid for complicating bronchiectasis, which may persist even with apparent recovery as judged by symptoms. Clubbing of septic type now appears so rapidly that changes can be noted almost from day to day up to gross "drumstick" terminal phalanges.

Disappearance of the annular shadow to ordinary film examination may be entirely misleading in summation of prognosis. Tomography or examination with lipiodol will often show that all that has happened is that the primary lung abscess is replaced by a bronchiectatic abscess, communicating with a dilated and infected bronchus. Herein lies the explanation of what is often misread as a re-exacerbation of the primary symptoms, but is really a secondary and dangerous bronchiectatic process. Stethoscopic signs will aid us to this conclusion. Just as the progress in primary bronchiectasis from dilatation to lung involvement was marked by the forward march of metallic rales from the beginning of inspiration to beyond its middle phase, so is the backward progress now evident, from alveolar spaces to bronchial tube, by the retrogression from mid-phase to beginning of inspiration of these same characteristic sounds.

Tuberculosis

The progress of tuberculosis differs widely from that of both lung abscess and bronchiectasis in physical signs, radiological findings, and pathology. The key to the understanding of all changes leading up to tuberculous cavitation lies in the study of the behaviour of the acini. Until their caseous content breaks down they are completely silent areas, although they impose a lack of movement on the affected side far beyond their actual extent. But Nature attempts to evacuate them immediately they begin to disintegrate, and each discharges into its corresponding bronchiolus respiratorius. Now appears the earliest stethoscopic sign of active tubercle in a fine sibilus heard in the second half of inspiration. As it is increased in intensity the deeper the inspiration, and reaches its loudest and its highest pitch in the last third of inspiration, it is entirely different from the sounds of ordinary bronchitis.

We have now seen how all these differing sounds, interfering with normal inspiration in differing phases, seem to have a definite correlation with the actual site of the initial lesion in each disease producing them. Bronchial dilatation in early bronchiectasis interferes with the first phase; lobular lesions in lung abscess with the mid-phase; and acinar lesions in tuberculosis with the last phase.

A film taken before disintegration of acinar lesions begins is generally of one of two main forms. The first will be typical of the fibro-caseous or proliferative form of the disease, and present a rounded area of loss of translucency, usually in the subclavicular region or near the apex of the lower lobe, on one side of the chest. This is known as the "Assmann focus." The acute, non-fibrous, or exudative type of infiltration will present, on the average, many areas not unlike bronchopneumonia. Although more woolly in their edges, they have more clearly defined translucencies between them than is the case in simple bronchopneumonia. In addition they are more numerous, and are generally more marked in or are confined to the upper and middle zones of the lung fields, as against ordinary bronchopneumonic distribution in the lower lobes.

It is necessary to follow separately these two types of disease in their progress towards established cavitation.

Acute Exudative Tuberculosis

Acute disease seldom produces a large cavity, although several individual vomicae may appear as if simultaneously, or in quick succession. This is because by its nature it lacks the organization, collapse, and consequent increase in intrathoracic negative pressure characteristic of the proliferative type. The inflammatory exudate filling the acini caseates and disintegrates freely, uncontrolled by fibrous tissue and its accompanying numerous giant cells. No barrier is set round it to protect surrounding lung tissue, and as a result disintegrated tissue fills the bronchi, and bacilli flood the lymph nodes in increasing numbers, causing them in turn to caseate rapidly. The disintegrating area has a moth-eaten, ragged outline, but now and again the process is so acute as to give the impression of a large "ticket-punch" hole. The pleura immediately adjacent is actively inflamed.

On the film such a cavity will appear as an area of comparative translucency among the scattered shadows already described. Sometimes it has no clearly defined edge beyond a ragged outline; but now and again a definite wall is seen, heavy-looking and of the density of pneumonic exudate, which, we have noted, is indeed its structure. It will then differ quite distinctly from that of chronic lung abscess on the one hand and the chronic tuberculous cavity on the other. It lacks the defined, organized inner edge of chronic abscess and does not appear within a circumscribed area of equal loss of translucency in an otherwise generally uninfected lobe. A later description of the chronic tuberculous cavity will be sufficient aid in this differential diagnosis.

Heavy hilar shadows will be noted, indistinct and confluent, although the right tracheo-bronchial group of glands may show up as a separate and fairly well defined entity. As there is no fibrosis, shift of the mediastinum is not present towards either side of the chest.

Physical signs are mainly stethoscopic. Clubbing of the fingers is generally absent beyond its first manifestations. There is little true dullness; lung movement is poor. The preponderant part of the infiltrated area is usually silent, although here and there the diagnostic sign of active infiltration will be heard. Over the site of the vomica localized pleural friction may be heard, but the diagnostic sign of active cavitation consists in a very circumscribed coarse bronchitis, which gives the impression to the listener that it comes from the depths of the lung tissue. He is hearing a true tuberculous bronchitis by the flooding of the bronchi with caseating exudate.

Chronic Fibro-caseous Tuberculosis

We have already seen that the usual site of the earliest lesion in proliferative tuberculosis is subapical in the upper lobe. This is the usual site of its cavity, although by the time of its formation infiltration and fibrosis have, in the majority of cases, spread far into the lower lung fields.

Sometimes the Assmann focus breaks almost immediately into cavity formation. It then shows on the film as a well-defined annular shadow, not thick in its outline, and usually with a fluid level. The average case, however, shows a slow disappearance of its regular annular outline: its edge becomes confused, its loss of translucency is no longer uniform, and its lower edges merge into shadows made by the increased blood supply of draining bronchi tracking towards the hilum. Already a slight but definite shift of the mediastinum towards the affected side can be seen, and viewing the films at some distance will throw into relief against a background of generalized loss of translucency

bunches of acini, organized or collapsed, and starting to fuse. This is because, from the first, fibrosis has attempted to keep pace with infiltration. Tuberculous granulation tissue has entered the bronchioles; empty acini have collapsed; others are unable to rid themselves of their exudate, which proceeds from caseation to fibrosis. The bronchial wall weakens, dilates, loses its powers of elastic recovery in expiration, and is pulled more and more outwards by the intrathoracic pressure, which is now aided by the surrounding organization. Neighbouring affected acini combine to a solid fused surround of the advancing cavity; more distant ones are scattered throughout the diseased portion of the lung amid more active and less fibrotic areas. Surrounding lung tissue shows much fibrosis. Bronchi show thickened walls, and overlying pleura is adherent, its layers being organized and increased in depth, often to a considerable extent.

Physical signs are in keeping. Typical tuberculous clubbing is present in a large proportion of cases, although in very advanced and long-standing cases superimposed lung infections may make it approximate to the septic type. There is marked displacement of the mediastinum to the affected side, or a less marked but appreciable shift to the more affected side in bilateral disease.

While the signs of active infiltration remain at the advancing edges of active areas, and the signs of fibrosis may be heard throughout the diseased portions of the lungs, these are generally restricted in extent, as against the real amount of involvement found by film examination. A fairly safe rule of thumb appears to be that signs heard above the clavicle mean that at least one-third of the lung is involved, and that signs heard below the clavicle mean that at least half of the lung is involved. Where laryngeal tuberculosis is present we may estimate the true extent as roughly three times that of our stethoscopic findings.

The development of the cavity is signified by the addition to these sounds of coarse metallic rales, again of the same character and quality as those noted in lung abscess and bronchiectasis, but now heard in the last third of inspiration, increasing in intensity the deeper the breath, and remaining, and even increasing in number and coarseness, after cough. In addition, many cases have showers of fine dry-sounding crepitations with the act of coughing, disappearing immediately inspiration begins. They are evidence of thickening and adhering pleura, which is shown on the film as a generalized, even, slight loss of translucency over the infiltrated and fibrotic lung.

The chronic tuberculous cavity shows up on x-ray examination as no other cavity does. It has usually a fairly wide but always well-defined wall, which on close inspection may be hazy in its distal borders, where changing densities show how the scattered nodules of organized and collapsed acini of the barrier are lying in a background of fibrosed lung and covered by thickened pleura. Viewing at a distance, however, throws these densities into strong relief against the background, thus producing a picture quite distinctive, and in itself diagnostic, of fibro-caseous tuberculosis.

Conclusions

Such, then, is an attempt at correlation of pathology with physical and radiological findings in one small part of the fascinating study of chest disease. It is, as indeed it must be, an individual attempt. To return to the simile of the jigsaw puzzle, it has placed personal values on the sets of pieces and the single pieces. Part of the charm of the game is that other players may set their own values but arrive at the same answer, which, as already said, must be the physician's decision on the individual patient's pathogenesis at the moment of diagnosis.

We can see how every game from the first has a definite effect on the playing of its successors. We learn gradually to attach special meanings to our own set of pieces which we call physical signs in the light of increasing use of the radiological set; we read new values into our films by applying to them these readjusted physical signs; and we add to both a freshened interest in living pathology. In other words, each game is a new experience, instructive, exhilarating, and whetting to the appetite for further and new problems. The number of these is so large that we need never fear that in our short time we shall solve them all: we have games for a lifetime.

TREATMENT OF HALLUX VALGUS DEFORMITY IN SOLDIERS

BY

R. BROOKE, O.B.E., M.S., F.R.C.S.

Lieutenant-Colonel, R.A.M.C.

A surgeon who has treated with success hallux valgus deformity of the great toe in civilian patients may be disappointed with the results he obtains when similar methods are used in the case of the soldier. Why should there be this difference? There are many possible explanations. One is that usually in civilian life no question of compensation arises in this type of case, and the patient is thus forced by financial necessity to get back to his job as quickly as possible; he will co-operate to the fullest extent in the after-treatment and will make the best of any disability which may remain. In the case of the serving soldier this incentive to get well quickly is absent. He has no financial worries, is usually comfortably housed in an E.M.S. or military hospital, is excused duties, drill, and marching, and yet is not confined to bed and is allowed considerable freedom which he is fit to enjoy. It is not surprising that he takes his time in getting well. He is unenthusiastic, perhaps lazy, and often perhaps completely uninterested in the treatment. This lack of co-operation may lead to a poor result, which soon becomes apparent to the patient, and on occasion he will exploit it to the full. The greatest caution is therefore called for on the part of the surgeon, especially where operative treatment is contemplated. Each case must be considered on its own merits, and those only selected in whom some degree of co-operation may reasonably be expected, after weeding out men who have a grouse against everything—Army life in particular.

An analysis of Army medical categories will show that a man may be placed in Category A1 if he has no foot defects, A2 if he is an A1 man with slight foot defects, C if he would be fit for a higher category but for marked foot defects. The ultimate aim of any form of treatment is threefold: to raise the soldier to a category higher than that in which he is at present; to prevent his being placed in a lower category; and, finally, to prevent his being put in Category E and boarded out of the Army. Even if his ultimate category is not one of the higher ones, treatment will be worth while provided the time taken over it is not too great.

To be eligible for the lowest category, C, he must be capable of carrying out a full day's work in his own arm for continuous periods without going sick. He must be able to wear and march in Army boots. This does not imply that Army boots are an additional burden which he must bear. They may be heavy but they are well designed, and it is not the boots that are in any way at fault. The soldier, it is true, refers all his foot troubles to his Army

boots. He may be boarded Category E because he cannot march in them, but this is only tantamount to saying that no treatment will offer any prospect of his walking in any other than special boots or shoes with reasonable comfort, and probably not even in these. It may perhaps be that through an error of judgment or an accident the treatment attempted has failed in its object, or was possibly unsound in its conception and under war conditions should never have been attempted.

A man working in a sedentary occupation in civil life may for many years carry on in comfort by wearing shoes, only to find that his feet will not stand up to the strain of wearing Army boots. The Army, for self-evident reasons, does not make an issue of shoes. Men who by wearing shoes could be employed in clerical or administrative duties are thus lost to the Service. Special boots, and even such appliances as arch supports, may be obtained in isolated cases, but the formalities connected with their issue are so great that, in practice, attention is confined to an attempt, by palliative measures such as foot drill and massage, and in selected cases operative treatment, to make the patients well enough to wear the ordinary boots supplied without these additions.

Palliative Treatment

In soldiers, in most cases, the deformity is of the acquired type and is moderate in degree, so that much can be done by well-planned and graduated active exercises, with preliminary thermotherapy, and faradism to the invertors of the foot and intrinsic muscles, which are also at fault. Active exercises may be taught to music, and it is an advantage to group patients together into classes for this purpose. Newcomers are encouraged by the progress which they see in others. A course of daily active foot-exercise classes will last for twenty-one days, and the less severe cases may have recovered sufficiently at the end of that time to return to their units. These are, however, long-term cases, and more than one course may be necessary to tide the patient over the period of foot-strain due to the sudden change from a sedentary occupation to an active Army life.

Operative Treatment

The patient is a young man and, speaking generally, the deformity is not in its advanced stages and arthritic changes have not yet supervened. There is a well-marked bunion, an outwardly overriding or underriding great toe, a varying degree of stiffness and pain, and an associated dropping of the anterior arch. The deformity is fixed, and cannot be corrected by passive movement. Operative removal of the bunion will ease the pressure of the boot on the tender and sometimes inflamed soft tissues and, followed by a short course of physiotherapy, may be all that is required to enable the man to return to duty and to wear Army boots with comfort.

Such an operation does not correct the valgus deformity of the great toe; nor, for that matter, do arthroplasties, in which the metatarsal head is partly removed and reshaped or the base of the proximal phalanx removed. Only in older patients with arthritic and painful joints are these operations of Mayo and Brande justifiable—the exception rather than the rule in soldiers—and the most that can be hoped for is that by removing enough bone the joint will be rendered flail and painless. The great toe ceases to act as a lever and is carried as a useless appendage. Failure to remove enough bone gives a painful and stiff joint—rather worse, if anything, than it was before. In both these instances the toe will be shortened but the valgus deformity will persist. It is difficult to understand why so much is expected from an arthroplasty of this important weight-bearing joint when the results of arthroplasties in other

weight-bearing joints, except in the hands of a few, are on the whole so indifferent. It is certain that, in general, such radical operations have no place in the treatment of hallux valgus deformity in the soldier. Apart from the removal of the bunion already mentioned, the less the bone is interfered with the better. If the deformity is fixed, and cannot be corrected by palliative measures alone, operative treatment should be confined to the soft tissues. Some form of tendon-reposition operation, combined with a capsulotomy of the outer contracted part of the capsule of the metatarso-phalangeal joint, such as Silver and McBride's operation, is all that should be attempted.

Tendon-reposition Operation

The valgus position of the great toe is maintained by the contracted parts of the capsule and ligaments on the outer side of the metatarso-phalangeal joint by the pull of the outwardly displaced tendon of the extensor hallucis longus

FIG. 1.—A Z-shaped incision is made in the tendon of the extensor hallucis longus. The abductor hallucis is exposed, and is incised near its anterior border.

and by the pull of the innermost tendon of the extensor brevis digitorum passing to the great toe, and, to a lesser degree, by the adductor hallucis muscle. The long flexor tendon is not an important factor, for it is retained in its correct axis by the groove between the two sesamoid bones, and thus the direction of its pull is not altered.

The capsule of the metatarso-phalangeal joint may be exposed through a three-inch vertical incision to the inner side of the extensor hallucis longus tendon, and the soft tissues separated from it round to the outer aspect. Here an incision, half an inch in length and vertical to the long axis of the toe, may be made from the contracted capsule down to bone, when the toe may at once be placed in the over-corrected varus position with the greatest of ease. No attempt should be made to sew up the gap in the capsule thus formed. The tendon of the extensor hallucis longus muscle is next exposed for a distance of three inches down to its insertion and divided by vertical and horizontal incisions as in a tendon-lengthening operation. By retracting backwards the inner margin of the incision the inner part of the abductor hallucis, which in this region is partly muscular and partly tendinous, comes into view. The tendinous portion is traced downwards to its attachment to the inner sesamoid bone, and is then incised horizontally over a distance of one and a half inches, rather nearer the anterior than the posterior margin of the tendon. The

smaller anterior portion of the muscle and tendon can then be pulled forward, and will form a loop through which the divided extensor hallucis longus is threaded from deep to superficial aspect, put on the stretch in the over-corrected varus position, and sewn again to the proximal end with three or four interrupted stitches of fine silkworm-gut (Figs. 1 and 2). The innermost tendon of the extensor digitorum brevis is divided and the wound closed.

The toe is splinted by a small wooden splint (half a wooden tongue depressor serves well for this purpose) placed along the inner margin of the great toe and fixed first to the toe and then to the foot by two pieces of narrow strapping. On the fifth day the patient begins to walk with the splint *in situ*. On the tenth day active exercises are begun, and from that time the patient walks barefoot, both indoors and out. The splints are worn continuously for four weeks

FIG. 2.—The capsule on the outer side of the joint is incised vertically. The tendon of the extensor hallucis longus is passed through the slit made in the abductor hallucis muscle from deep to superficial aspect, and sewn again to its peripheral end by three interrupted stitches.

and are removed only for remedial exercise treatment. For a further three weeks they are worn at night only.

The power of active adduction and dorsiflexion of the great toe returns rapidly, and in from five to six weeks from the date of the operation the patient is walking without pain and without a limp, and is fit to rejoin his unit.

Conclusions

If operative treatment of hallux valgus deformity in soldiers is contemplated, only those cases likely to operate in the post-operative treatment should be selected. The patients are young, and much more can be done with palliative treatment alone than is the case in civil life.

Bony operations involving removal of the base of the phalanx or partial removal of the head of the metatarsal bone are best avoided.

An operation of tendon reposition with division of contracted capsule of the joint is described.

Specific Psychological Data and Characteristics

Certain data commonly found in the whole series, regardless of the personality type concerned, appear worth recording.

1. *Eye Troubles in the Family.*—Of the total of 52 patients 9 stated that another member of the family suffered from night-blindness. In one of them, incidentally one of the best-adjusted of all, the patient's father, two brothers, and two sisters complained of the disorder. Complete blindness in near relatives was reported by 7, injury to the eye by 3, and severe anomalies of refraction by 8.

2. *Nervous Habits.*—Of the patients 23 were nail-biters as children, 1 a thumb-sucker, 15 were stutters, and 23 were fastidious about their food; in all, 38 were either nail-biters or stutters or were fussy about their food as children. As adults, 20 were still nail-biters (their nails were bitten down to the quick), 1 was a thumb-sucker, 9 suffered from speech disorders, and 15 were fussy about their food. Altogether 33 were nail-biters, had an impediment of speech, or were fussy about their food.

3. *Morbid Fears.*—If an allowance is made for minor degrees of fear of darkness (\times), which are so very common in children, fear that must be regarded as excessive ($\times \times$, $\times \times \times$) was found in 24 and very severe fear ($\times \times \times \times$) in 6 of the patients as children. It persisted into adult life to an unusual extent in 22 (very severely in 5). When on rare occasions they ventured out in the dark they kept to the middle of the road, unable to shake off a fear that men might be prowling about ready to pounce on them, and every harmless passer-by was regarded with fear and suspicion. Until they joined the Army four of the men slept with the light burning. The mother of one had to sit by his bedside until he fell asleep; another disturbed his comrades in the barrack-room by getting up at night to stoke the fire or switch on the light.

Unusual fear of injury was pronounced in 32 of the men as children and in 28 as adults. Afraid of getting hurt, they avoided fighting and rough games as children. As adults they are extremely careful in crossing roads and are generally told that they have too much sense of danger. They have an irrational fear of doctors, nurses, and hospitals, and are terrified of minor surgical operations. They cannot stand the sight of surgical instruments, blood, or accidents. An otherwise courageous man, a special constable before joining up, used to "shake like a leaf" if he had to take patients injured in accidents to hospital. Some have an unreasonable fear of dogs, others of being robbed of something precious (of what, they do not know). One man got into a state of panic each time his hair was cut.

In 5 of the patients concern about their eyesight appeared to be related to previous injury or severe visual disorder. In 12 others their fear of blindness was clearly irrational. Long before the onset of their night-blindness they took great care not to throw too much strain on their eyes, never took part in stone-throwing, kept out of dust-clouds, and wore eye-shades at their work. Even if they were of very limited means they con-

tributed generously to charities for the blind. One man always walked stooped; another was laughed at because he closed his eyes when boxing. An airman, previously fond of watching "dog fights" in the air, after his breakdown made himself "as small as possible" if enemy planes were overhead, and felt unable to look up. A man who previously had distinguished himself by bravery, after his breakdown went straight to bed when an air-raid warning was given, and covered his eyes with the blankets. Several of the men were terrified of bayonet practice because of potential injury to their eyes, and one made himself a laughing-stock by wearing his steel helmet all day long; he felt that it gave better protection to his eyes than the forage-cap.

Other fears often encountered in these patients are fear of heights, claustrophobia, fear of water, fire, contamination, and infection.

4. *Conflicts over Aggressiveness.*—Four of the patients were overtly over-aggressive in adolescence or adult life. Two of them liked to provoke brawls, in the course of which, however, they used to faint. Two were criminals: one of these, a practical joker, delighted in tipping water out of windows, tying people to chairs, or screaming in cinemas. The vast majority were unaggressive, over-compliant, soft-hearted individuals. In some of them their aggressiveness was more or less completely repressed. They could not bear to see anyone in pain. One, for example, had not visited the cinema for years because he could not bear the sight of atrocities on the screen. He took a job with the N.S.P.C.C., but had to give it up because he could not stand reading the reports. These men accordingly loathe warfare, and some of them considered seriously reasoning with the enemy if they came up against him. In others the repressed aggressiveness was expressed in fantasy. "Roaming through the fields alone all day," said one, "I would sit at my camp fire at night and think to myself: 'The last generation had a war, why shouldn't we?'" He fancied himself a great explorer, a soldier, a doctor in a slum practice, an adventurer on the high seas. One of the patients had chosen Napoleon as his hero, and another one, a puny little man, wanted to descend as a parachutist in the centre of Berlin and wreck buildings. A great number of men, displacing their aggressiveness from their inner world into the outer, suspected danger everywhere, and were, as already mentioned, subject to numerous morbid fears. Some of the men succeeded in diverting their aggressiveness into channels which were tolerable to them. Two of the most tender-hearted patients took to butchering, and another one similar in type, a solicitor, chose to prosecute people. Others, deprived of an external outlet for their aggressiveness and prone to self-punishing attitudes on account of their inner conflicts, directed their aggressiveness against themselves.

5. *Prying Interests, and Wish to be Taken Notice of.*—It is obvious that the interview method does not lend itself to a careful analysis of early prying interests. Only very few admitted early peeping pleasures. One of them, the practical joker, took a special delight in bathroom intrusions. The majority denied direct prying interests. More than one, however, had gone out of his way to take classes in human anatomy without actual professional interest in the study. Several had volunteered for first-aid work despite their professed horror at the sight of accidents. One made use of his position as an unqualified chemist's assistant to listen to the complaints of his customers and even to examine them. A surprisingly large number of patients (13) reported spontaneously that as children they had repeatedly been "ticked off" for their uncalculated inquisitiveness and curiosity, and that later in life they had an unquenchable thirst for knowledge. With a perhaps relevant frequency they showed as children a predilection for visual activities, such as drawing, sketching, and model-making, which afterwards in some cases had definitely influenced or shaped their lives. In one patient a gross inhibition of visual activity had occurred early in life: he could not bear to look at the sky, and all his life had walked with his eyes fixed on the ground.

Similarly most of the patients were inhibited in their desire to be taken notice of. They liked to keep in the background, and if made the centre of attraction they felt uneasily all eyes focused on them. A fair number were unusually bashful in stripping in front of others. Six patients, by contrast, were only happy if they could show off.

* Concluded from page 575.

Mode of Onset

Nine patients stated that they had been night-blind since childhood, and in 16 it began later in life but before the war; 13 noted their first symptoms when the black-out started, and 14 in the course of the war. The onset was gradual in 31 and acute in 21 patients. No definite correlation between personality types and mode of onset could be established.

In four patients night-blindness started following some eye disease, injury to the eye, or eye operations which themselves, in the opinion of the eye specialist, did not account for the disturbance of night vision. In three cases it was preceded by a serious accident and was accompanied by various nervous symptoms. Eleven times it occurred in the course of a nervous breakdown, with which it was clearly connected. One man, a tin-worker, attributed its onset to the glare in the factory, but there was strong evidence in favour of the hysterical origin of the disorder.

The onset of night-blindness in the course of a nervous breakdown observed in eleven patients deserves special consideration. The setting, in four cases, was that of men of unusual gifts who, after tremendous efforts, came up against a situation which for different reasons was more than they could stand. One man developed an acute anxiety state with night-blindness as a prominent symptom when one day, after many years of happy married life, he caught his wife with his best friend as her lover. In six others their neurosis and night-blindness seemed to be precipitated by terrifying war experiences, such as the sight of mangled bodies, close friends killed in front of them, the sight of destruction of their much-treasured property, etc. Twice night-blindness which had existed since childhood was aggravated by similar circumstances. Here are some brief examples:

ACUTE ONSET

An aircraftman aged 19, who had lived a reckless life and had knocked about the world in an ocean tramp, enlisted in the marine section of the R.A.F. and his ship was blown up by a bomb. He struggled in the water, watching his comrades dying one by one, while he himself felt apathetic, unafraid, and ready to die. After his rescue and return to this country his symptoms came on; he became afraid of everything, was sleepless and unduly fatigued, and at the same time he noticed that his vision in the dark, on which he had formerly prided himself, rapidly deteriorated until he was night-blind.

Another man aged 21, grossly over-dependent as a child but afterwards ostentatiously independent and fond of taking risks and of gambling, had always been keen on aeroplane models and aeroplanes, and was fortunate in securing confidential work in the R.A.F. which thrilled him and gratified his inquisitive nature. On being posted to an aerodrome in a heavily bombed area he, however, was exposed to a severe raid in which a direct hit occurred near him, and he witnessed the spectacle of mangled bodies lying around. Some of his closest friends were among the fatally injured. After this incident he began to have nightmares, tremors, sleeplessness, headaches, and night-blindness. Formerly restless and thirsting for action, he has lost his confidence, ruminates on the fate of the shot-down enemy, reflecting: "These poor blokes had fathers, mothers, and sweethearts."

A corporal aged 29, averse to any "damaging mischief" as a child and professedly unaggressive and unduly soft-hearted throughout his life, chose butchering as his career. He studied anatomy and physiology of cattle in his spare time and, as his interest grew, took classes in human anatomy and physiology. When one of his colleagues disembowelled himself by accident he was completely unperturbed. "Blood is to the butchering business what water is to a man who works on the street mains," he said. The incident prompted him, however, to join the St. John Ambulance Brigade. Anxious to be exempted from use of "aggressive weapons," in case of emergency he enlisted

in the Territorial R.A.M.C. before the outbreak of war. Fearlessly he attended the wounded under fire; while doing so, and just when lifting up a wounded officer, a bomb came down near him and killed the officer in his arms; in fact, the officer's body protected this man against the effect of blast. Shortly afterwards he began to suffer from night-blindness and photophobia.

CHRONIC ONSET

A soldier aged 21, quiet, retiring, shy, unaggressive, passive, and over-dependent, was pampered and spoilt by both his parents because of his delicate state of health. He is still nicknamed by his brothers and the neighbours "Mummy and Daddy's boy." He has always been haunted by morbid fears—fear of infection, of heights, and of policemen. If anyone speaks sharply to him he shakes all over. His main fear, however, is that of darkness. He has always slept with his head covered by the blanket, and he very rarely went out in the dark. His family lives at the top of a tenement. If, on rare occasions, he came home late at night, he called at the house of a neighbour, and she took him home, waiting at the bottom of the stairs until he had safely reached his parents' flat. The boys in the neighbourhood used to laugh at him about his timidity. He has always been short-sighted, and noticed difficulty in seeing in the dark for the first time when the black-out started. When he was on night patrol one of his comrades had to take his hand.

Another soldier, aged 25, had always had an intense longing for love. Resentful of the want of love at home, he repeatedly ran away, but he never got further than a few miles. As he was thin, weak, and miserable as a child, he was an easy prey for teasing and cruelty by other children. He envied other boys who were big and strong, and he hoped one day to be able to protect himself and others. His ambition was to be a boxer. He has always been terrified of darkness and unduly concerned about potential injury to his eyes. Until 12 years of age he was a bed-wetter, and he still sucks his little finger. After a weak attempt at work he gave it up at 16, and he has since been unemployed and unemployable. At 18 he fell off a tree during his first attempt at smoking, and ever since he has complained of backache. Two years ago he was seduced by his present wife. He has never been really potent. His wife called him daft, and said that he ought to be drowned. He somehow managed to get into the Army, but right from the beginning he has been unable to do any duty. N.C.O.s told him he should desert, as he would save money to the country. The patient's nervousness has become worse during the last six years. He complains of sleeplessness, anxiety, depression, and lack of memory. Both by day and by night he gets frightened—of what, he does not know. He has frequent nightmares, dreaming that black people are after him with spears. Before joining up he rarely left his house, because he was afraid of people. If anybody talks sharply to him he trembles and bursts into tears. He has repeatedly considered suicide, but for fear of hurting himself has always desisted from committing it. His night-blindness started two years ago in connexion with eczema of his eyelids.

One case may be given in slightly greater detail.

A soldier aged 25 lost his father when he was an infant. His father was reported to have been a "strong man"; once he had taken up a challenge to wrestle with a Russian bear in a show and had won a cup, which to the patient's great disappointment he failed to inherit. Stories about his father's feats were all the more awe-inspiring for the patient as he himself was sick and delicate as a child. Being of poor health and the only child, he was spoilt and pampered by his mother, to whom he was greatly attached. The punishing authority in the house was his grandmother, who, if he did something wrong, used to lock him in the cellar. "I used to scream the house down," he said.

As a boy the patient was timid, shy, retiring, over-sensitive, and easily reduced to tears. His only companion was a blind uncle, four years his senior. Working in a power station, this uncle had been "dazzled by the light and lost his eyesight." Children used to shout nicknames after them, and call them "Flash and Sparks." The thought that a fate similar to that of his uncle might one day await him struck him at times, and he used to think that he would rather kill himself than accept

anybody's help. In his spare time he liked to lend a helping hand to his mother, who often remarked that he should have been a girl. He preferred girls' company to that of boys. If on rare occasions he went out alone in the darkness he used to imagine that men were following him. "They might molest me; by that I mean force me into a car and kidnap me." Until 13 years of age he was a bed-wetter, and he is still a nail-biter.

For a time he thought of taking up boxing as a career, but being rather short-sighted and unable to see the ropes in the boxing ring, he "cut his throat" and had to give up the idea. He went into the cinema trade and became a re-winder. At 22 he joined the Regular Army "for adventure and excitement."

During the fighting in France he noticed the first nervous symptoms. He jumped at the least sound, trembled if he was addressed by N.C.O.s, and cried a great deal. The sight of "pieces of legs and trunks of men lying about" affected him very badly; he vomited frequently. On his return home people noticed that he had gone very thin; he rejected food and shunned company. He then went to Norway, where again he had a rough time. During a bayonet attack he stabbed three of the enemy and used the butt of the rifle freely. He wiped out two machine-gun nests by the use of hand-grenades. For bravery in this action he stated that he was recommended for the M.M. but did not receive it. Again the "ghastly sights" had a very bad effect on him. After the evacuation from Norway he made the acquaintance of his wife through a pen friendship, and he was more or less seduced by her. The morning after the first connexion with her he felt sore, and he had to hobble on two sticks for three days. Since their first intercourse his wife has refused herself to him and has been unfaithful to him. Although he realizes that he has made a wrong choice his only wish is to be reconciled to her, even if she should deny herself to him. Since then his nervousness has become worse: he shakes at the least noise and cries easily, and when air-raid alerts are sounded he goes to bed and covers his head with the blanket. During a recent leave he heard machine-gun practice; immediately he cowered down in a corner of the room. The patient is anxious to return to civilian life. He wishes to work in the telephone office in his home town, where among a number of women telephonists a job is waiting for him. He feels disappointed in the Army because his application to become a parachutist has been rejected. He would like to descend in the centre of Berlin and wreck important buildings. In case of an invasion he has planned to kill his family, his stepfather included, to prevent them from being raped.

His night-blindness started after an accident in Norway. One night his unit took shelter in the cellar of a house. As he came out of it the house was hit by a bomb and he was blown back into the cellar. Subsequently he was blind for two days, and ever since he has been unable to see in the darkness.

Psychopathology

It can be shown that all the patients examined were disturbed in the early stages of their emotional and instinctual development. Conflicts over dependence, over primitive aggressiveness, and over primitive sexual impulses were found to be prominent. Phenomenologically they were individuals who either had always been over-dependent on their mothers or had adopted an over-compensatory, reactive, and defensive attitude of virile independence. Their attitude towards their fathers was one of admiration mingled with fear and often overt hatred.

In the light of analytical knowledge, these facts, combined with the occurrence of nail-biting, stuttering, and food-fussiness in many of the patients, suggest an unresolved mother-child relationship which, originating at the breast level and continued into adult life, never lost its double-edged destructive and at the same time preserving character. These conflicts were accentuated when at a slightly later stage of development the patient encountered the conflicts arising from the triangular father-mother-son relationships. None of the patients passed through this phase successfully. A persistence of bisexual tendencies could be clearly seen in many of them. Their outward appearance of masculinity was often very delicately poised. On close examination it was found that underneath, throughout their whole lifetime, a continuous struggle against feminine and passive homosexual tendencies had been taking place.

Among their primitive sexual impulses which were prolonged into adult life, scopophilic and exhibitionistic tendencies, usually in a concealed but sometimes in a fairly overt form, were seen to be present to an unusual degree. The eyes of these patients became libidinized more than is usual. From time immemorial in folk-lore, mythology, and idiomatic language the close association between aggressiveness and seeing on the one hand and incorporating and seeing on the other has been generally recognized. The "evil eye" and the devouring look are well known. Moreover, the importance of the eye as a phallic symbol has been stressed by the analytical school. In consequence it seems conceivable that severe taboos imposed on early sexual impulses related to the eye, as in the classical myth of Oedipus, may lead to self-inflicted blinding—that is, night-blindness. The limitation of the patient's blindness to the night is not surprising, perhaps, when we consider that night is predominantly the time for sexual expression and that darkness is the best ally of the criminal aggressor. In keeping with this it can be shown in many instances that the onset of night-blindness was ushered in and often precipitated by a dramatic incident when the patient, confronted by the horrors of war, was unable to tolerate the sight of the fulfilment of his well-harboured and deeply repressed destructive fantasies. The onset also coincided with the collapse of a painfully and carefully created virile façade, which in the final breakdown gives way to complete feminine submission and reappearance of childlike dependence.

Discussion and Conclusions

1. *G. I. Scott*.—In only one of the 42 cases examined was there a true ocular cause for the symptom of night-blindness.

2. *B. Semeonoff*.—Although the number of subjects in the control group was small, fairly satisfactory standards of normal dark adaptation seem to have been established. There is a distinct break between the lowest adaptation measure (3.0) among the "B" cases in the control group and the cases classified as defective (2.1 and 1.0). In the night-blind group, again, the lowest "C" case (1.5) showed a marked difference from the highest of the "D" cases (0.8). If 3.0 is taken as the lower limit of approximately normal adaptation instead of 2.5, the lowest figure graded "B," 16 of the night-blind cases may be regarded as showing normal or near-normal adaptation. This number is raised to 24 if the remaining "B" cases are included. In other words, 40 to 60% of the night-blind men tested for dark adaptation showed little or no disturbance of this function.

This estimate is made independently of the ophthalmological findings, which account for certain of the cases of defective dark adaptation, and which have also revealed that the present method of testing, based on peripheral vision, was bound in certain cases to give very poor adaptation results.

3. *E. Wittkower, T. F. Rodger, and G. I. Scott*.—Of the 52 patients 34 were submitted to a joint ophthalmological,

FIG. 2.—Correlation between ophthalmic, dark-adaptation, and psychiatric findings.

I. No or minor ophthalmic findings; no or minor disturbances of dark adaptation.

II. Relevant ophthalmic findings; no or minor disturbances of dark adaptation (22 patients in Groups I and II).

III. No or minor ophthalmic findings; relevant disturbances of dark adaptation.

IV. Relevant ophthalmic findings; relevant disturbances of dark adaptation (12 patients in Groups III and IV).

psychological, and dark-adaptation examination (Fig. 2). Of the 34, 22—i.e., about two-thirds—had no disturbance of dark adaptation on testing or had disturbances within

the limits of those found in a control group of patients not complaining of night-blindness. Moderately high errors of refraction found in 6 of 22 men seem to be irrelevant for the disorder. Since the great majority of the 22 patients (20) suffered from fairly severe or very severe psychological disorders of a specific type, it is legitimate to assume that in these cases the complaint of night-blindness is of purely psychological origin.

Of the 34 patients 12—i.e., about one-third—had, on testing, disturbances of dark adaptation beyond the normal, established by a study of a control group. This group is of particular interest and importance.

Of the four cases showing "severe" disturbances of dark adaptation three exhibited typical tubular "hysterical" fields, although they had no difficulty in orientating themselves in daylight. The remaining man had a marked "functional" disturbance of vision in that he would only admit vision equal to 4/60, although there was no ocular cause to explain such defective vision—i.e., the ocular findings in all of these cases showed evidence of marked functional disturbance.

Of the eight cases showing "moderate" disturbance of dark adaptation, correlation with the ocular findings gives the following results:

1. One case of retinitis pigmentosa—that is, a true ocular cause for the defect.

2. One case of corneal scarring, sufficient perhaps to explain the defect.

3. Two cases showed evidence of functional disturbance in that there was defective vision for which there was no ocular cause.

4. Four cases had no ocular cause for night-blindness and showed no ocular evidence of functional disturbance. Of these four, however, two revealed well-marked evidence (other than ocular) of psychiatric disorder, and one was a very definite case of hereditary night-blindness.

It is therefore unnecessary to assume the existence of vitamin A deficiency to explain the dark-adaptation results; and, indeed, the possibility of vitamin A deficiency can safely be excluded, as all the men had an ample vitamin A supply and, considering the severity of their disturbance of dark adaptation, should have had other objective evidence of vitamin A deficiency such as xerosis of the conjunctivae or Bitot spots. Such evidence, however, was absent. The fact that the dark-adaptation test revealed diminished adaptation in neurotic as well as organic ocular disorders shows that it cannot be relied upon to indicate vitamin A deficiency. It is probable, though hitherto unproven, that the results of dark-adaptation tests may be influenced by mental mechanisms.

On the basis of the present study we venture to express the opinion that night-blindness as seen in this country, though phenomenologically the same, is aetiologically quite distinct from night-blindness due to nutritional causes.

Summary

A series of 52 unselected soldiers complaining of night-blindness were examined ophthalmologically, psychiatrically, and by dark-adaptation tests.

A. Psychiatric Examination.—1. The great majority of the men were found to suffer from severe psychological disorders. Using a modified Culpin scale, the severity of their disorders was classified as Grade 1 in 9, as Grade 2 in 12, and as Grade 3 in 31 patients. Of the 43 patients in Grades 2 and 3, 27 suffered from acute and chronic anxiety states, 8 were cases of conversion hysteria, 4 were cases of depression, and 3 were psychopathic personalities of the schizoid or over-aggressive type. Most of the men, quite apart from their night-blindness, were found to be

unfit for military service because of their psychiatric abnormalities.

2. Of the 52 men 27 gave a lifelong history of over-dependence. They were perpetual children or men with strong feminine tendencies. In 12 others, though he-men in appearance, their ostentatious independence was reactive and over-compensatory in origin. The remaining 13 patients were mixed reaction types.

3. Certain characteristics—nervous habits (nail-biting, speech disorders, food-fussiness), morbid fears (excessive fear of darkness, fear of injury, especially to the eyes), conflicts over aggressiveness and abnormal prying interests—were commonly seen, and long antedated the onset of the disorder.

4. The onset was gradual in 31 and acute in 21 patients. It occurred in 11 patients in the course of a nervous breakdown. In 6 cases it was preceded by terrifying war experiences, such as the sight of mangled bodies.

5. The psychodynamics of the disorder were discussed.

B. Ophthalmological Examination.—Of the patients examined ophthalmologically 42 can be grouped as follows: (1) no ocular findings, 13; (2) one eye defective, other eye negative, 6; (3) minor errors of refraction, 11; (4) marked errors of refraction, 11; (5) severe eye anomalies, 1. In only one patient, a case of retinitis pigmentosa, was there a true ocular cause for the complaint of night-blindness.

C. Dark-adaptation Examination.—Dark-adaptation tests were carried out in 40 of the patients. Of these, 16 showed mild disturbances of dark adaptation and 9 showed none—i.e., in 25, as compared with a control group, the dark adaptation on testing was within the limits of the normal. Moderate disturbance of dark adaptation was found in 11 and severe disturbance in 4 patients.

D. Joint Examination.—1. Of 34 patients studied jointly 22 had no relevant disturbance of dark adaptation on testing. Almost all of them suffered from severe psychiatric disorders of a specific type. Of the remaining 12 patients with definite disturbances of dark adaptation on testing, one was a case of retinitis pigmentosa and another a case of hereditary night-blindness; in practically all of the others, although their psychiatric disorders appeared to be less severe than in the main group, were found severe disturbances of eye function which are generally regarded as "hysterical" (tubular fields, etc.).

2. No evidence of vitamin A deficiency as an aetiological factor in night-blindness could be obtained in the series studied. The value of dark-adaptation tests for the discovery of night-blind patients and as an indicator of vitamin A deficiency appears doubtful. Most cases of night-blindness seen in this country are probably of psychological origin.

One of us, in carrying out this research, was supported by a grant from the Halley Stewart Research Fund, and his sincere thanks are due to the Trustees. Our thanks are also due to Lieut.-Col. A. M. Simson, R.A.M.C., and to Prof. James Drever, for providing facilities for the research.

CLOSED-PLASTER TREATMENT OF BURNS OF THE EXTREMITIES

BY

T. J. ROULSTON, B.Sc., M.D. Alberta

Resident Surgical Officer, E.M.S.

The treatment of wounds by closed-plaster technique has received much attention of recent years. I have recently had the opportunity of applying the same form of treatment to cases of burns of the extremities admitted to an F.M.S. base hospital.

Following enemy action at sea a number of cases with burns caused by steam were admitted to this hospital. Of these, one which showed partial and full skin loss in feet and ankles was treated by the closed-plaster method seventeen hours after injury. Treatment consisted in cleansing with saline and removing blisters. All burnt areas were covered with vaselined gauze, and plaster-of-Paris was applied from the tips of the toes to the knees. The patient made an uneventful recovery. Plasters were removed on the fourteenth day, when the burnt areas were found to be completely healed and ankle movements were full and painless. A large number of cases which were involved in the same incident were admitted to a hospital elsewhere and were treated by various well-accepted methods. The interval between injury and initial treatment was from twelve to twenty-four hours. Some of these cases developed sepsis, and several were transferred to this hospital, at periods varying from three to twenty-one days after injury, for further treatment.

After admission here the closed-plaster method was applied only to grossly infected cases in which there was no regression of sepsis, the affected limbs being extremely painful on movement and in all instances showing joint deformities. No other method of selection was used for this series. In this manner 16 cases were treated—a total of 26 limbs, consisting of 11 hands and wrists, 3 wrists, 8 feet and ankles, and 4 complete upper extremities. No other form of treatment was applied either externally or internally, with the exception of silver nitrate to burn down the occasional small granulations and liquid paraffin

to maintain pliability of skin after the plasters were removed.

In trying to assess the extent of full skin destruction in the earlier cases a great deal of difficulty was encountered, particularly because of the superimposed infection present. All areas had definitely suffered partial skin destruction. The only occasion on which full skin destruction could be ascertained was when cases required more than one plaster application. An estimate was made from the size of areas of clean granulation tissue seen at the first plaster change. But by this time a large amount of epithelization had undoubtedly taken place, so an accurate estimate of the initial full skin destruction could not be made. Later cases did not offer so much difficulty, as the infection was in a chronic phase and granulating areas were present where there had been complete loss. How much of this was due to destruction by burning and how much to superimposed infection cannot be stated.

Method of Application

All cases were handled in the operating theatre; burnt areas were cleansed with saline, either by douche or sponge, and surrounding undamaged skin with soap and water. The affected areas were then covered with two thicknesses of gauze impregnated with petroleum jelly or liquid paraffin. Plasters were applied, and an endeavour was made to obtain absolute immobilization of the affected part by including the joint above and below it in the plaster. This was not possible in two cases in which the skin of the elbows and upper arms was involved. Absolute immobilization could only have been obtained by shoulder spicas, which were not warranted owing to the general condition of both patients at the time of application.

The position in which joints were immobilized varied with the position of the burnt area and the possibility of contracture formation. It also varied with the anticipated duration of treatment in plaster, bearing in mind that at each plaster change all joints were to be put up in positions different from the previous ones, so as to ensure as much mobility as possible when the areas healed. Early cases, in which a short period in plaster was anticipated, were put up in such a position as entirely to counteract the possibility of contracture. Where longer periods of immobilization seemed likely this was not attempted at the first application, the position being improved at change of plaster so as to reach an optimum position gradually.

A difficulty which arose with the ordinary methods of applying plaster was the danger of injury to the newly formed epithelium by cutting instruments. This was avoided by the use of plaster slabs, especially for hands and forearms. In these cases a palmar slab was applied from the finger-tips to the upper forearm, and was moulded with the joints in the desired position. When this had hardened the edges were greased with petroleum jelly. A dorsal slab was then applied and an ordinary gauze bandage wrapped around the forearm. The hand portion was well moulded between the fingers, which were previously separated by pieces of cotton-wool between the finger-tips. Extensions were made to include the elbow-joint and arm when desired. In this way the plaster could be removed easily by separating the slabs. In cases of feet and legs a fairly thick posterior slab and then circular plaster bandages to a thickness which could easily be cut with a plaster-knife were applied. These plasters included the toes, leaving only the extreme tips available for inspection. Plasters were changed every ten to fourteen days, depending on the amount of discharge and the condition of the plaster. The following outstanding features were noticed during the course of treatment by this method.

Comparative Freedom from Pain

In 13 cases there was immediate relief from pain—so much so that the whole mental attitude of the patient was completely changed. Movements in bed were free and painless. The only complaints in some cases were a sensation of heat, especially in the fingers, for the first two or three days and a soginess inside the plasters several days after application. Previously in most cases strong analgesics had been necessary for the control of pain. It was possible to discontinue the use of these immediately, soneryl and aspirin sufficing to relieve insomnia where present.

In 3 cases, however, there was complaint of pain, but to a much less degree than before the application of plasters. In one of these, a case of burns of the feet and ankles, plasters were removed for investigation. This revealed considerable pocketing of pus under tan which had been applied as initial treatment. The tan was removed and plasters reapplied. This procedure was followed by complete relief of pain. The other two cases had extensive burns of both hands, forearms, and upper arms. These patients complained of pain not in the completely immobilized forearms and hands but in the region of the inner aspect of both elbow-joints, though it was much less severe than before plasters were applied. This pain was remedied by postural immobilization of the shoulder-joints. After the first change of plaster the pain recurred slightly, but soon disappeared.

Ease of Nursing

Before plasters were applied some cases needed changing of outer dressings at least three times a day because of

the profuse discharge, and there was also the periodical complete changes of dressing in all instances. This was entirely eliminated. The ward sisters repeatedly spoke of the ease with which the necessary attention could be given to these patients, who could now be moved about freely in bed without causing pain. No special instruction, supervision, or apparatus was required in the wards, and it was very apparent that large numbers of burns could easily be handled at one time, even in a busy hospital, without causing any undue strain on the nursing staff.

Improvement in General Condition

With the relief of pain and toxæmia there was in all cases immediate improvement in general condition, appetite, and sleep. That toxæmia was reduced to a minimum was evidenced by the speedy return of pulse and temperature to normal. In 10 cases the temperature ranged between 100° and 102° before plaster application. In 5 cases it became normal in two days; in 3 others normal was reached in three days. Where this was not the case septic burns of other areas not treated in plaster were present, but a rapid improvement was noted.

Flexibility of Joints and Absence of Contracture Formation during Treatment

Certain precautions were taken during treatment. To be assured of the greatest flexibility joint positions were changed at each plaster reapplication; and, to prevent contracture formation, joints were put up in a position that counteracted this possibility.

On admission all cases showed pronounced limitation of movement and the rapid progression of dropped wrists

Table Summarizing the Cases

Case No.	Age	Area of Burns Treated in Plaster	Initial Treatment	*Period after Injury	Mobility of Joints	Days in Plaster	Immediate Result	End Result
1	19	Dorsum of foot. Dorsum and lateral aspect of ankle	Closed plaster	17 hours	Limited owing to pain	14	Completely healed. Ankle movements full	Same
2	33	Feet and ankles. Anterior surface of left leg	Triple dye and AgNO ₃	4 days	Movements painful. Tendency to drop-foot	23	Healed. 5 degrees limitation of dorsiflexion	Full movements in 7 days. Walking normally
3	19	Left foot and ankle	"	4 "	Movements very limited and painful. Tendency to drop-foot	23	Two small granulating spots. 5 degrees limitation of plantar flexion and dorsiflexion	Completely healed. Full movements in 7 days. Walking normally
4	47	Both feet and ankles	"	4 "	Feet dropped. No movements, owing to pain	23	Two small granulating areas. Slight limitation of movements	Completely healed. Full movement in 7 days. Full on exercises and massage for old-standing pyelitis
5	37	Left foot	Tannic acid and AgNO ₃	13 "	Foot painful and dropped. Very little movement possible	16	Completely healed. Dorsiflexion 10 degrees. Plantar flexion 15 degrees	Full movements in 10 days
6	27	Right hand and wrist	"	6 "	Completely immobile, owing to tan and pain	10	Completely healed. All movements 70% of normal	" " "
7	25	Both hands and wrists	Vaselined gauze	6 "	Wrists dropped. Fingers immobile	20	Healed except for small granulation on dorsum of right hand	Completely healed. Movements 95% of normal in 10 days
8	26	" "	" "	6 "	Wrists dropped. All joints only slightly mobile, mainly due to pain	10	Completely healed. Movements 70% of normal	Passive movements full. Active movements 95% of normal in 7 days
9	30	" "	" "	6 "	" "	Rt.-10 Lt.-18	Right, completely healed. Left, all but an area on palmar surface of wrist	Completely healed. Full movements in 10 days
10	25	Dorsum of left hand	Charcoal and AgNO ₃ mixture	11 "	Flexion of m.-p. joints 20 degrees. Finger-joints less limited	16	Completely healed. Joint movements 80% of normal	Full movements in 7 days
11	28	Right hand and wrist	Vaselined gauze	18 "	Very little movement in all joints. Fingers semiflexed, owing to contracture	10	Nearly full extension. Flexion 50% of normal	Finger extension 95% normal. Finger flexion 70% normal. Wrist movements full
12	35	Both hands and wrists	Tannic acid and AgNO ₃	18 "	Very little movement in all joints. Contractures starting	10	Healed except for small granulation on right ring finger	Completely healed. Full movements in 14 days
13	38	Both wrists	" "	18 "	Dorsiflexion nil on both sides	10	Healed. Dorsiflexion 5 degrees. Palmar flexion full	Dorsiflexion full in 10 days
14	40	Right wrist	" "	18 "	Dorsiflexion 5 degrees	10	Healed. Dorsiflexion 15 degrees	Dorsiflexion full in 7 days
15	23	Both upper limbs	Triple dye and AgNO ₃	14 "	Movements of all joints greatly limited	Lt.-10 Rt.-25	Healed except for small granulations. Left elbow 90 degrees of movement. Right elbow 60 degrees of movement	Left limb full movements in 10 days. Right elbow and hand, full movements in 10 days
16	22	" "	Tannic acid and AgNO ₃	21 "	All joints completely immobile. Gross evidence of contractures		Still under treatment	Right limb practically healed. All but forearm on X. healed

* Beginning of plaster treatment.

and feet. This was at first considered to be due to muscle spasm; but it was found, when plasters were first applied, that even under anaesthesia there was still definite limitation, although greater range of movements could be obtained. When changing plaster, and after the termination of treatment, flexibility of joints was quite obvious, particularly in hands and fingers, even after long periods of immobilization. Thus in no case did the immobilization result in increased stiffness; in fact, all movements were much better after the period of rest. This was so obvious that some patients remarked that the limb which had been in plaster felt more useful than the corresponding one which had not been so treated.

No contractures developed in patients who received plaster treatment within the first three weeks. In later cases contractures had already started to develop, particularly in areas where there had been full skin loss. In these plaster provided an excellent method of control.

Healing

As previously mentioned, only grossly septic burns were put in plaster, less severe lesions being treated chiefly with vaselined-gauze dressings. When both types existed in the same case it was repeatedly observed that the severe lesions healed as quickly as the much less severe ones not treated in plaster.

The rate of healing varied with the severity and extent of the burnt area, the degree of sepsis, and the interval between injury and the beginning of plaster treatment. Eight burns of the hands and fingers extending on to the wrists and forearms healed in ten days, except for an area of granulation tissue on the palmar surface of a wrist in one case. This healed in a further eight days in plaster that immobilized the wrist-joint only. Two other hands and fingers with burns and sepsis of greater severity healed in eighteen days. In these, at the time of plaster change, areas of granulation tissue were present on the dorsum of the hands and palmar surfaces of the wrists, involving one-quarter to one-third of those surfaces. Burns of the wrists healed in ten days. All feet and ankles healed in twenty-three days, and showed large areas of granulation tissue when the plaster was changed. In all cases in which granulation tissue was present the ingrowing epithelium did not reveal any signs of limitation, as is seen definitely during other methods of treatment. In most it appeared to be invading the granulation tissue in an irregular protrusive manner, and later these same areas showed epithelization that was complete except for occasional very small granulations which healed in two to three days after application of silver nitrate. This new epithelium was well formed, smooth, and pliable, and there was very little evidence of scarring even over areas which had been granulating. Hypersensitivity of this epithelium was less than in cases not treated in plaster.

In one case of burns involving the whole of both upper extremities plaster treatment was begun three weeks after injury. The right limb showed numerous areas of granulation tissue varying in size from one to three inches in diameter at the first plaster change, and was practically healed in twenty days. The left limb showed clean granulation tissue involving the whole forearm and lower part of the arm at the first change of plaster. At the end of twenty days only three-quarters of the forearm was involved, and it was considered advisable, because of the lateness of starting treatment, to "seed"-graft this area and reapply plaster in an effort to speed up epithelization.

Return of Function

This also varied with the severity and extent of the burnt area and the degree of sepsis, but especially with the

interval between injury and application of the closed-plaster treatment. In cases which were received within one week of initial treatment function that was nearly normal was obtained in seven days and full function shortly after. In cases received later than this return to full function was slower.

Summary

A description is given of a series of 16 cases of infected burns of the extremities in which closed-plaster treatment was used.

The difficulty in assessing the degree of burn in infected cases is commented on.

Details of technique are described.

Certain definite advantages of the method are claimed—namely, freedom from pain, rapid improvement in general condition as evidenced by fall in pulse and temperature, ease of nursing (important where large numbers have to be dealt with), maintenance of joint flexibility, and prevention and correction of contractures.

The results in this series are such as strongly to suggest that epithelization and return of function are quicker than in cases treated by other methods.

My thanks are due to Lieut.-Colonel G. M. Millar for his co-operation and for permission to publish these cases.

Medical Memoranda

Crohn's Disease with Acute Obstruction

The following case is placed on record because of its uncommon nature.

CASE REPORT

The patient, a soldier aged 27, gave a history of vague attacks of umbilical pain of increasing frequency and severity over a period of three years. These attacks occurred every few months and lasted from one to two days. He never vomited and he had no other symptoms. Two years previously he had sought medical advice, but radiological examination of the gastrointestinal tract was negative. No cause for his symptoms was found at that time, and when he entered the Army a year later he appeared to be quite fit.

While in barracks in February, 1941, he developed pain similar to his previous attacks and was admitted to our care, with the diagnosis of recurrent appendicitis. When seen by us he had had severe umbilical colic intermittently for six hours, and had vomited once. His temperature was 99°, pulse 110, and respirations 24. On examination the tongue was coated and the breath offensive. There was no abdominal pain or rigidity between spasms, but he complained of soreness on pressure of any part of his abdominal wall during a pain. This was no worse at any one point than another. On rectal examination nothing was found. A blood count showed 15,650 leucocytes per c.mm., with a predominance of polymorphonuclear cells.

Acute appendicitis seemed to be the most likely diagnosis, but as this was by no means certain the abdomen was opened through a right lower paramedian incision. The peritoneal cavity contained a considerable amount of cloudy fluid. About six inches of the lower ileum was acutely inflamed and thickened; the bowel above this portion was dilated and that below collapsed. One foot of bowel was resected, a side-to-side anastomosis made, and the abdomen closed. The patient made an uneventful recovery.

Examination of the specimen showed an inflamed piece of small intestine, with partial obstruction due to thickening of the wall and reduction of the lumen for approximately two inches. Above this the muscle wall was hypertrophied. The obstruction was completed by a pea in a small pouch immediately above the narrow portion, otherwise the lumen was patent. The mucous membrane was covered by rather ragged ulcers, and the muscular wall was thickened, hard, and rather translucent. Microscopically there was an extensive old fibrosing granulomatous lesion. A few recent typical tubercle follicles were seen in the lymphatics deep to the muscular wall, but no tubercle bacilli were detected.

in the sections. The mucous membrane was partly necrotic. Many large foci of lymphocytes were seen in all the layers, and there was an extensive eosinophilic infiltration. Except for the eosinophilia the appearances were characteristic of tubercle; but this type of lesion is usually regarded as non-tuberculous, and was described by Crohn as regional ileitis. Our patient showed no sign of tuberculosis elsewhere.

COMMENTARY

Crohn's disease is not common, and for it to appear as an acute obstruction is still less so. Usually the patient is operated upon through a small incision for chronic appendicitis, and the appendix is removed without the real nature of the disease being realized. The condition then goes on to fistula formation or the patient has repeated attacks of subacute obstruction. This might well have happened in our case had not the pea caused an acute obstruction at a relatively early date.

CECIL W. WARD, M.B., Ch.B.

Leeds.

DEREK T. THOMAS, M.R.C.S., L.R.C.P.

Depressed Fracture of the Sternum

John B. Hartzell (1935) stated that fracture of the sternum is an exceedingly rare condition, and that it is often complicated by fractures of the ribs or spine. Holderman (1928) found sixty-two cases among 46,237 fractures of all types—an incidence of 0.075%. The following case of depressed fracture of the sternum due to indirect injury may therefore prove interesting.

CASE REPORT

The patient, a woman aged 67, was admitted on May 5, 1941, after having fallen downstairs. She was suffering from shock, and had considerable difficulty with respiration. She complained of pain over the upper dorsal region and severe pain and tenderness over the upper end of the sternum, where there was a depression about an inch deep in place of the normal angle of Ludwig. There were no bruises or abrasions of the skin over either the sternum or the dorsal spine. Clinical examination revealed no involvement of the spinal cord. The patient had apparently fallen with her head flexed forwards, as in gambolling, the fracture being due to hyperflexion. A radiograph revealed a fracture of the sternum at the junction of the manubrium and the body (the upper fragment being displaced behind the lower) and a compression fracture of the fifth dorsal vertebra.

On May 7 a plaster jacket was applied in hyperextension; this extended to the mandible anteriorly and to the lower lumbar region posteriorly. Difficulty was experienced in obtaining enough hyperextension owing to pre-existing kyphosis, but the patient was much more comfortable after the application. A later radiograph showed a very satisfactory position: the depression was corrected, and the manubrium and body of the sternum were in line.

I wish to express my thanks to Mr. L. A. Dingley, senior honorary surgeon to the hospital, for his kind assistance and permission to publish this case, and also to Sister Burrows of the x-ray department.

Reviews

CARDIAC CLASSICS

Cardiac Classics. A Collection of Classic Works on the Heart and Circulation. With Comprehensive Biographic Accounts of the Authors. By Frederick A. Willis, M.D., M.S., and Thomas E. Keys, M.A. (Pp. 858; illustrated. 50s. net.) London: Henry Kimpton. 1941.

To have compiled a work of this character must have involved great labour and research. The authors are therefore to be warmly congratulated on having accomplished so much. In a concise form they have put together important extracts from all the writings of physicians or surgeons who have contributed to our knowledge of the structure of the heart or the diseases affecting it. Such extracts may surely be happily termed "cardiac classics." Omitting all tentative references to the heart in times before Harvey, they begin with the story of the circulation of the blood by giving a full translation of *De Motu Cordis* and end with James Herrick's description of coronary thrombosis. There is a picture of each writer who has extended our knowledge of the structure of the heart or its diseases, together with a short account of his early education and life's work, which is often of particular interest. Then there are a number of excerpts from his writings, sometimes of special value, as in the case of Heberden, where a full account of angina pectoris is given also of Austin Flint, who wrote widely on all phases of medicine, though his name is most thought of in association with the presystolic murmur sometimes accompanying aortic regurgitation.

It is curious to note how in the case of so many of these physicians, apart from their writings in connexion with the heart, they have contributed much of importance to other departments of medicine. Thus Corrigan (1802-80) in addition to his masterly account of aortic regurgitation also wrote on fibroid disease of the lung, which was for long known as "Corrigan's cirrhosis." Again, William Gowers, so distinguished as a neurologist, is here included because of his description of the retinal vessels in cases of hypertension. It might have been well to have given more than a passing notice to Vieussens of Montpellier (1641-1710) and to Albertini of Bologna (1672-1733).

In a useful appendix these cardiac classics are correlated with other historical events. Thus Auenbrugger's introduction of percussion was contemporary with the Seven Years' War, and Laennec produced the stethoscope and auscultation two years before the death of Napoleon. In this way the authors draw medicine into connexion with general history, and prevent it from becoming too much isolated from the main current of the life of the world.

R. O. MOON.

EPILEPSY AND MIGRAINE

Science and Seizures: New Light on Epilepsy and Migraine. By William Gordon Lennox, M.D., Sc.D. Hon. (Pp. 258; illustrated \$2.00.) New York: Harper and Brothers. 1941.

Dr. Lennox, who for more than twenty years has taken the lead in the investigation of epilepsy in the United States, has written this book in order to make available to all who are interested in epilepsy, which includes patients and their relatives and social workers as well as doctors, the latest ideas on the nature of this disorder which recent investigations have brought to light. It is thus a popular book of a kind with which we in this country are not familiar, but throughout it is entirely scientific. Four-fifths of it

At the suggestion of Dr. G. Jedlewski, medical adviser to the Polish President (M. Raczkiewicz), a special medical board has been formed in London to prepare plans for fighting epidemics which may break out in Poland at the end of the war, and thus to prevent the spread of infectious disease to Western Europe and Great Britain. The board, acting in conjunction with the Ministry of Health, will also collect medical supplies so that immediate help may be ready at the end of the war.

devoted to epilepsy, and this is considered in all its aspects. In particular the significance of the disordered brain rhythms which have been revealed by electro-encephalography is explained in relation to the risks of the hereditary transmission of the disease. It is estimated that one in every two hundred inhabitants of the United States suffers from epileptic seizures, but for every single patient there are twenty apparently normal persons whose abnormal brain rhythms show that they are both potential epileptics and potential transmitters of epilepsy. Dr. Lennox aims at replacing irrational fear by humane scientific understanding in both those who suffer from epilepsy and those who have to deal with them.

The section on migraine is much shorter and less comprehensive. The affinities of this disorder with epilepsy are perhaps less close than Dr. Lennox maintains, and electro-encephalography does not seem to have brought them any nearer together. It may perhaps be doubtful whether the benefit which epileptics may derive from being told that their disorder is allied to migraine is not counterbalanced by the effect upon sufferers from migraine of learning that they are afflicted with a disease akin to epilepsy.

The book is well written and contains a bibliography almost exclusively of American work. It makes accessible much recently acquired knowledge not otherwise so easily obtainable.

PRACTICAL GYNAECOLOGY

Textbook of Gynaecology. By Wilfred Shaw, M.A., M.D., F.R.C.S., F.R.C.O.G. Third edition. (Pp. 616; 255 illustrations and 4 coloured plates. 21s. net.) London: J. and A. Churchill, Ltd. 1941.

To celebrate its fifth year this already popular textbook has appeared in a new and third edition. It has been revised throughout, and in spite of rationing the five-year-old is as attractive in appearance as its predecessors. The general arrangement of the book has been preserved, and emphasis continues to be given to anatomy, physiology, and pathology, while the outstanding quality of the illustrations remains a feature. The student who masters the basic subject of anatomy and physiology does not necessarily become a good doctor, and many textbooks which are excellent for reference purposes are but poor inspiration for the embryo clinician because this fact is overlooked. Dr. Wilfred Shaw teaches the importance of accurate observation and attention to detail and guides the reader to those paths of logical deduction which lead to sound diagnosis and treatment. For this reason alone the book can be commended both to medical students and to practitioners.

Those everyday problems associated with irregular bleeding, vaginal discharge, sterility, and fibroids are particularly well surveyed. Conservative critics will with some justification challenge the statement that myomectomy should be performed in preference to hysterectomy only when the patient insists on retaining her uterus. The technical difficulties and dangers of myomectomy in capable hands are exaggerated; they are not sufficient to warrant such an attitude. A useful summary is given of contraceptive methods, but it is surprising to find that the much-discussed "safe period" receives so little attention. Those details which are given are misleading because they are inadequate, and it is to be hoped that this section will be revised for the next edition.

The chapter dealing with gynaecological diagnosis should be read many times. It emphasizes the importance of an accurate history, gives a broad review of symptomatology, and concludes with an excellent account of the technique for investigation of a case.

A guinea spent in adding this book to the library would be money well invested.

Notes on Books

First published in 1917, *Surgical Nursing and After-Treatment*, by Mr. H. C. RUTHERFORD DARLING, has now reached a seventh edition (J. and A. Churchill, 10s. 6d.). The author is surgeon to the Prince Henry Hospital and the New South Wales Masonic Hospital, Sydney, and it was originally written in accordance with the syllabus for the final examination of the Australian Trained Nurses Association. The text has been thoroughly revised in the light of recent clinical experience and with co-operation from surgical and nursing colleagues. As was said in these columns when noticing an earlier edition, the book abounds in useful tips and advice based on well-proven details of technique, and particular attention is paid to post-operative care. While primarily addressed to nurses, it should also prove very helpful to students and junior members of the medical profession.

It is only to be expected that in time of war there should be a spate of small handbooks of psychology written in a popular vein. Dr. K. O. NEWMAN'S pamphlet, *Mind, Sex, and War* (Simpkin Marshall, 3s. 6d.) is entertainingly written, if a little too replete with purple patches. He analyses with discrimination the reaction of different temperaments to the war situation. We heartily agree that one of these people is a public nuisance—the man or woman who needlessly interferes with our private existence by unnecessary and sometimes even ruinous restrictions, and who seems to prefer it when people don't like them. To such, war indeed offers abundant opportunity. The publishers do some disservice to the author by claiming too much for him and by unfairly stating that "the practice of [other] popular writers on psychology . . . is to tell the reader what he wishes to hear."

Mr. H. N. Linstead, secretary of the Pharmaceutical Society of Great Britain, has assembled in workmanlike fashion the material for a volume commemorating the centenary of his Society on April 15, 1941. It has eighty-four large pages. The introduction, headed "A Century of Service," takes the form of a general survey of the Society's development—rather than a detailed historical record duplicating Mr. Howard Bayles's elaborate review printed at the time of the centenary. The commemoration itself is reported at length, with the full text of Mr. Linstead's play "Jacob Bell and Some Others," which was produced at the Conway Hall, London, on April 15, and afterwards at the Crane Theatre, Liverpool. There is much other interesting matter, grave and gay, and the volume is enlivened with many excellent illustrations.

Six years ago Major F. MITCHELL-HEGGS classified and arranged in subdivisions the papers set at the final examination for the London M.B., B.S. during the preceding fifteen years, and published them in book form with some preliminary advice and information. He has now brought out a new edition (J. and A. Churchill, 7s. 6d.) analysing the questions set during the years 1925-40, omitting those set in 1920-5. In the interval between the two editions the final examination for these degrees of London University has been reconstituted, and now consists of three parts instead of two.

Films picturing the morphology of the lower animal creation have been much appreciated by cinematograph spectators, and the interest so awakened has aptly enough found expression in a demand for more light upon the origins and development of these diverse organisms. The further information desired is contained, as touching the invertebrates, in the sixpenny Pelican book *Cine-Biology*, by three authors (J. V. DURDEN, MARY FIELD, and F. PERCY SMITH). The first type in order is amoeba, sexless and therefore immortal. Next comes paramecium, subject to death but revived by conjugation, which is the dawn of sex. The life history of the liver fluke is called a "desperate survival," which indeed it is. Among the arthropoda figured and described are daphnia of the rolling eye, cyclops with its pair of eyes fused at the last into one to justify its name, the shrimp, which goes back to the Devonian, the king crab, the dragon fly, and the emperor moth. The authors write with a lively enthusiasm, which is communicated to the reader and should serve to carry him through or over the more specialized passages. The text is set off and elucidated by 119 excellent photographic reproductions.

Preparations and Appliances

ELECTRIC PROBE FOR LOCATION OF METALLIC FOREIGN BODIES IN THE TISSUES

Surgeon Lieutenant R. C. J. HILL, R.N.V.R., writes:

The accurate location of foreign bodies in the tissues often proves difficult even when the surgeon has at his command the resources of a well-equipped radiological unit; and to the surgeon in the field, or in a ship, where such facilities are limited, any device which might assist him in his search should be welcome.

Over forty years ago, during the Boer War, an instrument known as the "telephone probe" was devised, and this in principle was probably similar in its mode of action to the "radio probe" described by Dr. James Hall in his letter to the *British Medical Journal* published on November 2, 1940 (p. 611). Practical experience in this ship stimulated research on reading Dr. Hall's letter, but though various types of wireless sets and circuits were tried with the co-operation of the torpedo department, satisfactory results, as described in the letter, were not obtained. After further experiments the electricians finally suggested an instrument which "divined" the presence of metallic bodies by the completion of an electrical circuit when two probes came in contact with it. The instrument went through many vicissitudes before satisfactory results were obtained, but in its final form it has proved its value, with certain limitations, and is light, compact, and easily sterilized.

The instrument consists of two silver-plated probes, one within the other. The outer probe, of 4 mm. diameter, is insulated internally by a fibrous material which is impervious to moisture and heat. The inner probe has a slightly beaded end, which projects to a distance of 2 mm. beyond the end of the outer probe. The latter is secured by a screw to a socket in the handle of the instrument, while the longer inner probe passes further down, and is screwed to a thread on a watch spring. The watch spring and the outer probe are in connexion with a battery within the handle which is also connected to a small torch bulb. Very slight force, such as is experienced when the projecting inner probe comes in contact with a foreign body, depresses the watch spring; and when both probes are flush, and therefore in contact with the metal object, the circuit is completed and

Diagram of electric probe, approximately half size, except for the probes, which have been drawn on a slightly larger scale to indicate clearly the insulation. The fibre insulating material is shown in solid black. A = Bulb. B = Thumb-screw to secure outer probe. C = Torch battery unit cell. D = Watch spring to which inner probe is secured. E = Bayonet catch.

the bulb lights. The handle and fittings are made of brass, and the former holds a unit cell of the ordinary torch type. This can easily be removed from the base of the instrument by releasing a bayonet catch.

The whole instrument can be sterilized by boiling, preferably in oil, but since this appears to have an adverse effect on the tension of the spring, in practice it has been found sufficient to boil the probes and immerse the handle in spirit. Just before

use the handle is covered with a sterile jacket, the probes passing through a small opening, while the light is strong enough to shine through the material.

In actual practice it is difficult to locate small fragments of metal, since they must be of a diameter greater than that of the outer probe, while the force required to depress the inner probe, though slight, appears sufficient to move such particles along the tissue planes. It is considered, however, that the removal of such fragments, in the absence of infection, would not normally be attempted. Where large fragments are concerned it should be possible to locate the metal with the probe and then decide on a line of approach, since so long as the probe is in contact with the metal the light will remain burning.

It is not considered that this instrument is infallible, but it has been of assistance. In any case it is a rough affair, made in the ship from material available, in the spare time of a chief artificer, to whom all credit is due.

INTRAMUSCULAR DRIP GLUCOSE SALINE

Dr. M. SARWAR writes from the War Memorial Hospital, Wrexham:

Intramuscular glucose saline has often been recommended for marasmic infants in whom gastro-enteritis precludes retention of fluids and nourishment either by mouth or per rectum. The usual method used was injection of glucose saline in 30 to 40 c.cm. doses into the flanks every four or six hours. This method had the following disadvantages: (1) danger of sepsis because of repeated injections, (2) frequent disturbance of the very fragile infant, (3) pain. Considering the above I thought a method of continuous administration on the pattern of intravenous drip would be very useful, which I tried and found to work very well.

The details are as follows: the equipment is the same as for intravenous saline administration, namely: (1) a bottle of dextrose saline (vaccoliter type), (2) glass dripper, (3) rubber tubing, (4) pinch cock (screw type), (5) glass connexion, and (6) fairly long hypodermic needle (2½-in. size).

Method.—The apparatus is set up as for intravenous drip, with due aseptic precautions. The saline is allowed to run free until there is no air in the tube or the needle. It is then turned off. The skin of the infant's flank is prepared with spirit in the usual way and the needle inserted between the layers of the abdominal muscles. The saline bottle is then raised and hung up at a height of about 2½ feet. The curtain stand at the head of the swing cot usually serves the purpose quite well. The fluid is then allowed to drip at the rate of ten to twenty drops to the minute by bits of elastoplast over the glass connexion. The apparatus can thus be worked for about twelve hours or more as need be. Periodic watch should be kept on the skin, and the drip stopped if the skin is very distended. It can be restarted when the oedema goes down, or the site of the needle varied. Three to five units of insulin can be injected into the bottle and shaken up if deemed necessary.

This plan does away with all the disadvantages of the usual method described above; besides, it delivers the saline at an even, gentle rate, giving it enough time to get spread out under the muscles and making absorption easier. A further advantage is that it reduces the work of the nursing staff.

I have to thank Dr. D. B. Evans for his kindness and for permission to use this method on his patients.

H. C. A. Lasser and J. Bang (*Norsk Med.*, 1940, 81, 2130) state that between January 1, 1934, and January 1, 1940, 9,826 patients were under treatment for scarlet fever at the Blegdams Hospital, Copenhagen. Of these, twenty (0.2%) developed complications in the central nervous system. In 1939 the incidence of these complications was 0.7-0.8%. All the patients showed pleocytosis with predominance of lymphocytes in the spinal fluid. In six the pleocytosis was the only indication of infection of the central nervous system, while ten had clinical signs of meningitis without focal lesions, and four presented evidence of focal processes. The seasonal incidence of the complications did not coincide with that of poliomyelitis.

THE NUTRITION SOCIETY

[FROM A CORRESPONDENT]

The first scientific meeting of the Nutrition Society, of which the foundation was reported in the *Journal* of October 11, and was also made the subject of editorial comment in the same issue, augurs well indeed for its future. It may have been in part a feeling that the occasion will prove to have been a historic one, in part a wish to bear public witness to the importance of nutrition, in part an interest in the subject of the actual meeting—"The Evaluation of Nutritional Status"—and in part just natural human curiosity, but the result was a meeting of some 250 people in the Physiology Department at Cambridge, a meeting as distinguished in many of its personnel as it was representative of the large and diverse bodies of workers in the field of nutrition. Physicians and surgeons lunched with statisticians and experts in animal husbandry; at tea-time opinions and information were exchanged between biochemists, medical officers of health, and plant pathologists: the several interesting demonstrations—including a live sheep complete (or incomplete) with gastric fistula—were visited by dietitians, physiologists, Government officials, organic chemists, and economists. It is doubtful if even in Cambridge or Oxford there have often collected together so varied an assortment of experts for a single symposium on a particular subject.

Programme of First Session

The programme laid down by the energetic organizers of the meeting was closely followed, except for the regretted absence of Sir John Orr, chairman of the Society's provisional committee, away on urgent Government business, and for the usual unavoidable slight lag behind scheduled times. Even so, the inaugural ceremonies, the three main papers, the six subsidiary contributions, lunch, and tea were all disposed of between 11 a.m. and 5 p.m.

It is very much to be hoped that some record of this discussion will be kept and published, as well as the more formal contributions presented by the nine speakers, three on each of the three subdivisions of the main subject. Of these contributions coming in from the wide territory that comprises laboratory research, clinical investigation, and animal experiments in barn and field, it is not possible to give even an outline that could begin to do justice to their interest and importance. For it is just the details, rather than the general broad principles they illustrate, that constitute much of the importance of these contributions. Where, unexpectedly, the same observation or deduction is made independently by experts in widely separated parts of the territory, there is to be found immediately an indication for further investigation, possibly of a collaborative nature, of a problem that has more than a parochial or specialist interest. Thus, for example, Dr. C. Crowther's insistence that the effect of adding a single nutrient to an animal's diet must be dependent on the nature and amount of the other nutrients in that diet seems to be an expression of a more general nutritional law that almost certainly underlies the facts in the minds of later speakers when they stressed the relative importance of multiple deficiencies compared with simple uncomplicated avitaminoses.

The claims of the "laboratory school," represented by Dr. Harris's contribution, and the clinical findings of Dr. B. F. Platt, with his wide experience of deficiency diseases in China and East Africa, find reconciliation, if this is needed, through the intermediary of such analytical minds as Dr. Sinclair's. The wider and correlated use of available methods, bound up with his obvious determination to examine all such methods with ruthless objectivity, will surely reveal that Dr. Harris and Dr. Platt are approaching the same phenomena from different ends. Integration alone will enable us to discover at what stage of a dietary insufficiency the biochemical changes depicted by Dr. Harris's methods become accompanied by the clinical stigmata revealed under Dr. Platt's examination.

Physiological Stress and Subclinical Conditions

A point brought out by all three speakers in the clinical section was the effect of physiological stress in revealing or accentuating those subclinical conditions that are the result of single or multiple dietary deficiencies. Thus Dr. W. C. W. Nixon spoke of pregnancy, Dr. R. H. Dobbs of the rapid growth and intense metabolism characterizing infancy and childhood, and Dr. Platt of heavy manual labour and the onset of hot humid weather as tending to throw up previously masked disturbances due to some dietary imbalance. In some similar way the artificial conditions of stress under which many domestic animals are reared—the goal being, as Dr. Crowther indicated, primarily not the good of the animal itself, but satisfaction of its owner's economic requirements—may themselves accentuate the handicaps already imposed by a diet and environment departing from those natural to the species. The combined strain of intensive milk or egg production and stall or battery feeding might be expected to reveal pre-existing vitamin and mineral deficiencies. But, as Mr. H. H. Green showed, particularly in his references to phosphorosis, coastal sickness, and swayback, even "natural" conditions of feeding may not prevent the outbreak of indubitable deficiency diseases, only to be combated by raising the status of poor marginal pastures nearer to that of the best. Here it is that the work of the nutritionist concerned with the problems of human and animal health brings him in close contact with the interests of the agricultural expert.

Dr. John Hammond's revelations of how the experimenter may make play with the shape as well as with the weight of adult animals—pigs or sheep, for instance—by submitting them to dietary deprivations at different periods of growth lead one, by perhaps a legitimate line of speculation, to wonder what light such animal experiments may have to throw on the permanence or otherwise of the changes brought about in human infants, adolescents, and young adults as the result of the kinds of nutritional defects discussed by Dr. John Yuckin and Dr. G. W. Robertson, who have been investigating in particular the partial nyctalopia of vitamin-A deficiency, and also the lowered haemoglobin level due to iron lack.

The Society's Prime Functions

Enough has perhaps been written to show that this symposium most certainly fulfilled its two main functions. The first was that to which reference was made by Sir Charles Martin, who took the chair at the morning session in place of Sir John Orr, being succeeded in the afternoon by Sir Joseph Barcroft, and also by Sir Frederick Gowland Hopkins, who at Sir Charles Martin's invitation opened in the morning both the particular work of this symposium and the Nutrition Society's public activities in general. The first function was to bring together the many disciplines required for exhaustive study and effective action in the fields of animal and human nutrition. The second function, clearly felt by the founders of the Society and its energetic committee, though not always explicitly stated, was to make the exponents of these several disciplines realize not merely that they have much to learn from one another, but that many or all of their activities may be frustrated unless they exchange views and information and also actively collaborate in pursuing investigation and in securing the practical application of its results. If for no other reason, this symposium was highly encouraging because it revealed how large a number of the country's most distinguished nutritionists are convinced of the truth of this view. To have at one meeting, all attending with the utmost care to a very varied list of communications, past and present Presidents of the Royal College of Physicians, professors of medicine, physiology, and biochemistry, members of Government scientific staffs and administrative grades, scientists from the laboratories of food and drug manufacturers, teachers of domestic science, the "planners and plotters" from experimental agricultural research stations, public health experts—this made the symposium, despite its essentially unofficial nature, almost a British counterpart, on a smaller scale and covering only a corner of the vast field, of that National Nutrition Conference for Defence at Washington in April last.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 1 1941.

VITAMIN-E THERAPY IN NEUROMUSCULAR DISORDERS

A symposium on vitamin E which was published in 1939¹ was largely concerned with its endocrine and obstetric actions, though Vogt-Möller referred briefly to its employment in disease of the nervous and muscular systems. The value of vitamin E in the prevention of abortion—its original application in man—remains unproven, and during the last two or three years interest has been focused on its action in neuromuscular disease. The occurrence of nervous and muscular disorders in experimental vitamin-E deficiency has been known since 1928, when Evans and Burr² reported paralysis in the offspring of rats which had been kept on a diet lacking this vitamin. In these animals Lipshutz³ demonstrated degeneration affecting chiefly the ascending and descending vestibular, tecto-spinal, rubro-spinal, and dorsal ascending tracts. Several workers subsequently observed a muscular dystrophy, without nervous changes, in young rabbits, guinea-pigs, and dogs reared on a diet deficient in vitamin E. These dystrophies could be prevented, and in the earliest stages cured, by adding the vitamin to the diet. Ringsted⁴ in 1935 and Burr, Brown, and Moseley⁵ in 1937 reported the appearance of paresis in adult rats deprived of vitamin E: a full clinical and pathological account of this disorder was given by Einarson and Ringsted⁶ in 1938. They described pronounced flaccid paralysis and wasting of the hind limbs, with ataxia, some hypo-aesthesia, and loss of hair and trophic ulceration over the hind quarters. Administration of vitamin E could arrest the paralysis in its earliest stages only, without bringing about recovery; in the later stages it had no effect on the progress of the disease. Einarson and Ringsted compared the early changes to those arising in tabes dorsalis, and the later ones to those in amyotrophic lateral sclerosis and progressive muscular atrophy. The purely muscular dystrophy unaccompanied by nervous changes seen in young rabbits and guinea-pigs deprived of vitamin E may be compared to the juvenile muscular dystrophies of man. Antopol and Unna's⁷ observation of foci of muscle atrophy in vitamin-B₁₂-deficient rats, and the production of tremors and convulsions from overdose of it, led to the suggestion that deficiency of this vitamin also might play a part in the pathogenesis of muscular dystrophies.

The resemblance of these experimental disorders to spontaneous nervous and muscular diseases in man was so striking that clinical trial of vitamin E was not only appropriate but imperative. It is true that in the experiments on animals treatment had been disappointing in so far as vitamin E had not cured the disorders once they were established. In adult rats and in puppies the dystrophies can be arrested only in the early stages, though in young rabbits and rats advanced cases of muscular dystrophy have responded to α -tocopherol, the active principle of vitamin E, and Morris⁸ has reported the cure of muscular dystrophy in adult rabbits with the same substance. Moreover, in cases of muscular and nervous atrophy in man there are usually no signs of dietary deficiency, and Denker and Scheinman⁹ could obtain no evidence of this in their cases of amyotrophic lateral sclerosis. Bicknell,¹⁰ on the other hand, maintains that many people consume a diet deficient in foods which are rich in vitamin E. He gave half an ounce of fresh dried whole-wheat germ twice daily to eighteen patients with muscular dystrophy, four with amyotrophic lateral sclerosis, two with tabes, one with peroneal muscular atrophy, and one with amyotonia congenita. Nine of his cases of muscular dystrophy improved after treatment for two to eighteen months, one relapsing when the treatment was stopped. In the other nine there was little or no improvement after treatment for six to sixteen weeks. Only one of his cases of amyotrophic lateral sclerosis clearly showed improvement (after seven months' treatment); in one the improvement was doubtful; and two of the patients died. In the other diseases no effect was observed after eight weeks' treatment, though the patient with amyotonia congenita seemed rather stronger. Wechsler, after a preliminary report¹¹ on five cases of amyotrophic lateral sclerosis, in two of which improvement had followed treatment with α -tocopherol, reported¹² twenty more cases of this disease. He gave 50 to 100 mg. of α -tocopherol, partly by mouth and partly intramuscularly, and a diet rich in vitamin E; six cases were unaffected, three were arrested, and eleven were improved. In some cases the improvement was considerable, as in one practically bed-ridden woman aged 36, with a year's history of illness, who became able to walk and even do some housework after ten months' treatment. Stone¹³ reported improvement in five patients with muscular dystrophy treated with 2 c.cm. wheat-germ oil daily: he also gave vitamin B₁ and thought that this helped. He stated that in one case of old anterior poliomyelitis there was lessening of muscular atrophy with the same treatment.

To many readers of these papers the results seemed too good to be true, and time has unfortunately confirmed their scepticism. Later reports have been uniformly negative as to suggest that these earlier successes can be explained by the remittent nature of neuromuscular disorders and by the psychological stimulus of new therapy. Shelden, Butt, and Woltman¹⁴ treated eight cases of muscular dystrophy, six of amyotrophic

lateral sclerosis, and four of progressive muscular atrophy with 180 c.cm. wheat-germ oil by mouth daily, and with 100 mg. of *a*-tocopherol intramuscularly twice weekly, for periods of three to five months, but none of their cases showed any improvement. Denker and Scheinman¹¹ treated eleven cases of amyotrophic lateral sclerosis with 55 to 175 mg. *a*-tocopherol daily, partly orally and partly by intramuscular injection. In no case was any improvement noticed. One of their cases was very mild and of only six months' standing, but was not helped any more than the others. They add a note on four other more recent cases treated with 250 mg. *a*-tocopherol and 100 mg. vitamin B₁ daily, but the results were equally disappointing. Ferreebe, Klingman, and Frantz¹² treated thirteen patients with progressive muscular dystrophy, seven with progressive muscular atrophy, and six with amyotrophic lateral sclerosis: they gave two tablespoonfuls of wheat-germ cereal, 70 to 100 mg. *a*-tocopherol, and 10 to 30 mg. pyridoxine hydrochloride (vitamin B₆) daily by mouth, and 100 to 200 mg. *a*-tocopherol intramuscularly once or twice a week. The period of treatment extended over two to fifteen months. In none of these cases was there significant improvement; in ten of the cases of muscular dystrophy and six of progressive muscular atrophy there was no deterioration. Two important investigations in this country, both of which gave negative results, have been published this summer. Worster-Drought and Shafar¹³ treated twenty-five cases of motor-neurone degeneration with vitamin E in the form of synthetic *a*-tocopheryl acetate or wheat-germ oil. The cases included bulbar paralysis, progressive muscular atrophy, and amyotrophic lateral sclerosis; only two showed definite improvement, and progressive deterioration occurred in all nine cases of bulbar paralysis. The authors point out that, though the prognosis of motor-neurone degeneration is always grave, the rate of progress varies, and periods during which no advance of the disease takes place are by no means uncommon in the absence of specific treatment. Fitzgerald and McArdle¹⁴ treated ten cases of muscular dystrophy and ten of motor-neurone disease with either vitamin E or vitamin B₁, or with a combination of the two, without obvious improvement. Their results are of particular value because they were controlled by the estimation of the daily output of creatine and creatinine. In diseases of muscle creatine is found in excess in the urine, the amount depending on the bulk of improperly functioning muscle. Rabbits with nutritional muscular dystrophy excrete an abnormal quantity of creatine, which falls dramatically within a few days of the administration of *a*-tocopherol. No such improvement occurred in the human cases treated by Fitzgerald and McArdle.

When these and other figures in the literature are summed up the clinical statistics of vitamin-E therapy in neuromuscular disease are indeed disappointing and reveal no significant difference from the course of the untreated disease. No biochemical evidence has been produced of any action of vitamin E, natural or synthetic, on neuromuscular disease in man. It is probable that the place of vitamin E in the index of treatment

will not finally be decided until simple means are available for analysing the amount of the vitamin in the body fluids and tissues. We do not doubt that vitamin E is an important food factor, but we find nothing yet to persuade us that any human disease, or any disturbance of childbearing or locomotion in man, is due to deficiency of vitamin E or is alleviated by treatment with it. Similar provisional judgment must be passed on vitamin B₁, now known as pyridoxine, which has been advised in Parkinson's syndrome and in a number of other neurological disturbances in addition to those already discussed; here, too, the early promise has not been confirmed."

ECONOMY IN DRESSINGS

It is a pity that the Select Committee on National Expenditure cannot be persuaded to look into the use of surgical dressings in wartime. Its comments might be pungent and informative. The amounts of cotton and other imported materials used for surgical dressings must bulk as large as the imports of drugs, but so far they have not been subject to the same carefully planned economy. It is perhaps inevitable that the treatment of wounds should be on a cost plus percentage basis, but certainly more might be done to communicate to the surgeon a sense of the cost of dressings in money to the patient, hospital, or insurance fund, and in imports and irreplaceable stocks to the country. It is inexcusable that materials should still be wasted in techniques which are discredited or superseded. M.R.C. War Memorandum No. 3 says laconically that boric acid in boric lint is wasted. Nevertheless we have it on reliable authority that 44% of all prescriptions for lint are for boric lint and that prescriptions for boric lint constitute over 6.5% of all the prescriptions for dressings under the National Health Insurance Act. It is perhaps misleading to say that the boric acid is wasted, for when the doctor orders two ounces of boric lint the patient actually gets only just over an ounce of lint and the rest boric acid. But to weight lint with boric acid, which must be imported, seems both extravagant and foolish in wartime, for there can be few who now seriously believe in the antiseptic or healing virtues of boric acid. Nor has any pharmacologist the slightest doubt that the belladonna in belladonna plaster is wasted, and that the same green colour and psychological effect could be produced by an extract of lawn mowings, yet an important proportion of our supplies of this precious drug is still being diverted to this purpose. The surgeon is entitled to reply that no up-to-date casualty department ever uses boric lint or belladonna plaster, but his own foibles are equally susceptible to criticism. The hospital treatment of burns has been debated with almost religious fervour, but we have no figures for the relative cost in time, money, and materials of treating a burnt hand with plaster-of-Paris, Bunyan bag, sulphonamide and saline packs, or the antiseptic pellicles of which sulphadiazine in triethanolamine is the latest example. Few hospitals go to the trouble of sorting soiled dressings from dirty dressings so that the merely soiled may be used again.

Oily dressings are now used on a wide scale in the treatment of burns, septic wounds, and compound fractures, either alone or in conjunction with substances such as flavine, a sulphonamide, bismuth, zinc oxide, and iodoform. There is good reason to believe that the action of the oil is mechanical, forming a surface on which lymph does not adhere and clot. The current prices per gallon of oils, without tax, are approximately: vegetable oils, 6s. 6d. to 7s.; liquid paraffin, 8s.; crude cod-liver oil, 9s. 6d.; pure cod-liver oil, 19s. 6d. Cod-liver oil is in short supply and is urgently needed for human and animal nutrition. The revival of the treatment of burns by carron oil suggests that the cheaper vegetable oils are not unsuitable, nor is there any convincing evidence that fish-liver oils improve healing to a degree commensurate with their rarity and cost. Why, then, are they still being used for external applications? One of the most popular oily dressings at the present time is tulle gras, and this likewise appears to be equally effective whether or not it contains halibut-liver oil and balsam of Peru. Tulle gras consists of nothing more than curtain muslin steeped in soft paraffin, and the prices charged for proprietary brands of this material are fantastically high.

Newer materials such as artificial silk and the transparent wood-pulp wrapping known by the proprietary name of cellophane have not been exploited in this country, though it is known that artificial silk bandages are used by the Germans. Clothes are rationed, and menstrual diapers, in short supply, may soon be made from sphagnum moss, but clean abdominal incisions may still be seen covered with wads of cotton-wool and many-tailed bandages. It seems certain that sooner or later a drastic cut must be made in materials for surgical dressings, and it would be well for plans to be laid to deal with such an emergency. At present the facts are not available. To begin with we need a survey of a suitably chosen sample, in the statistical sense, to show what kinds of dressings are being used in the home, the workshop, the practice, and the hospital, and for what purposes. The next step would be the costing of different methods of dressing lesions from inception to healing. Discussions should then be held with the Ministry of Supply to discover which potential materials are plentiful, such as plaster-of-Paris, hypochlorites, and sodium sulphate, and which are wanted for other purposes, such as cotton-wool, phenol, and fish-liver oil. Experiments would be necessary in many instances, so as to avoid fiascos like the use of preparations of glycerin of tannic acid on burns of the hands and face. A short memorandum would then be prepared laying down standard methods of treatment; demonstrations of methods would be instituted, and quotas would be established on this basis. So far the attention of surgeons in this country has been directed too exclusively to the formation of centres at which patients are treated by specialists, to the advantage of both patient and specialist. Such methods may win the peace but it is doubtful whether they contribute much to winning the war. A raising of the general level of prophylaxis against wound and ward infection, and of economy in treatment, would be much more immediately useful, even though less academically interesting.

NIGHT-BLINDNESS

Few affections have a literature of such great antiquity as night-blindness. Various Egyptian papyri, including the Ebers papyrus, refer to it, and ox-liver was recommended for treatment. Descriptions of the condition and of liver therapy are also found in Hippocratic writings and in the records of ancient Chinese medicine. Liver therapy for night-blindness appears to have been prescribed throughout the Middle Ages, but fell into disrepute by the beginning of the last century; it is not mentioned in Mackenzie's classical *Treatise on the Diseases of the Eye* (1830). The significance that night-blindness has assumed with the advent of black-out conditions helps one to appreciate how important the affection must have been to earlier generations who had no brilliantly lit cities and were in any case largely rural. Moreover, it was not until 1853, when the ophthalmoscope established retinitis pigmentosa as a distinct entity, that a clear separation could be made into a form of night-blindness that had no complications and a more serious type which developed into the ultimately total or subtotal blindness of retinitis pigmentosa. The fear that a first experience of night-blindness engendered is well reflected by Mackenzie: "The first attack of the disease generally excites great alarm. The patient . . . finds his sight fail, and as evening advances becomes almost completely blind. The medical attendant . . . is often as much amazed and little less alarmed than the patient. . . . To the joy of all concerned the patient wakes in the morning with his sight perfectly restored. But again on the approach of evening, symptoms are perceived of returning blindness. Night after night the blindness returns, and becomes more and more complete . . . vision is more and more impaired; and if neglected or mistreated, the disease ends in incurable amaurosis. . . . Mr. Bampfield infers that, under proper treatment, the prognosis may always be favourable."

The ophthalmoscope, which solved so many problems and rendered many more meaningless, clearly postulated the problem of "essential" night-blindness at a time when social conditions made it an affection of decreasing urgency. When the night-blindness of retinitis pigmentosa—in which it is the first symptom of a progressive and grave affection—was distinguished as a separate entity there remained two clear-cut types. In 1838 Florent Cunier had published a pedigree of seven generations of the Nougaret family, showing eighty-six night-blind persons in a group of 629. Apart from this hereditary type there was known also an epidemic night-blindness affecting fatigued armies and civilian populations (such as sections of the Russian peasantry) suffering from "fatigue and want of sleep." Individual cases were also recognized as occurring in sailors, in whom "sleeping on deck is blamed as a cause." Night-blindness was also regarded as a symptom or precursor of scurvy. The association of xerosis of the conjunctiva with night-blindness was noted by Bitot in an outbreak of the condition in children at a Poor Law institution at Bordeaux during 1859-61. Two years after Bitot's publication (1863) Gama Lobo asserted that xerosis occurring in Brazilian slaves resulted from lack of

able and sufficient food. In spite of these early observations investigations into the aetiology of xerosis and of essential night-blindness tended to be independent studies, as xerosis is not always present or obvious. Subsequent workers have, however, reported so many instances of epidemic night-blindness in ill-nourished populations that, even without the validity of the therapeutic test of vitamin-A administration, the role of nutritional deficiency as the underlying factor in epidemic night-blindness came to be recognized. The conception of night-blindness as a deficiency disease unified the scattered and disconnected observations collected over centuries. That conception, elaborated before 1914, was verified by the outbreaks of night-blindness during the famine conditions on the Continent in the course of the last war and its aftermath. A particularly detailed study of the epidemic in Vienna during 1919-24 was made by Birnbacher, who, among others, found liver, cod-liver oil, butter, and other articles rich in vitamin A prompt and effective remedies.

The two clear-cut types of essential night-blindness—the hereditary and the nutritional—have been more fully elaborated of late years. Inheritance of night-blindness may be dominant, as in the Nougaret family and in many other recorded instances; recessive, when it is often associated with myopia; and sex-linked, when the disability is transmitted through unaffected daughters of affected males to some of their sons: this type, too, appears to be associated with myopia. The nutritional type, vaguely recognized in antiquity, was proved experimentally by Holm (1925) as due to vitamin-A deficiency by testing the ability of rats to jump off a table in a dim light. Rats on diets deficient in vitamin A developed well-defined night-blindness (after previous exposure to bright sunlight); this disappeared with the administration of vitamin A. The night-blindness was shown to be associated with retarded regeneration of visual purple (Fridericia and Holm, 1925), and extensive studies have since appeared on the role of vitamin A in the cycle of bleaching and regeneration of visual purple (Wald, 1935). The possibility that night-blindness is an early sign of vitamin-A deficiency led to studies of the range of dark adaptation in the general population as evidence of vitamin-A deficiency (Jeans and Zentmire, 1934; Frandsen, 1935). These studies revealed widespread subclinical vitamin-A deficiency in the general population, easily overcome by the administration of additional vitamin A. Refinements of the technique for testing dark adaptation and a more detailed understanding of the process have come from Lecht and his associates.

It is now clear that improvement in the symptoms of night-blindness does not always follow quickly on the administration of vitamin A; occasionally there is a latent period of as long as two months.¹ A survey of newer aspects of technique and problems of dark adaptation is given by Mandelbaum.² That night-blindness and xerosis are associated effects of vitamin-A deficiency is obvious from both experimental and clinical studies. In contrast to the accepted views, which regard night-blindness as the earlier symptom, Kruse³

suggests that slit-lamp studies of the conjunctiva and cornea in vitamin-A deficiency reveal characteristic lesions long before the formation of Bitot spots, which in fact must be regarded as the end-stage of a continuous range of appearances beginning with conjunctival injection. These studies are of significance because they may supply a simple and objective means for the diagnosis of night-blindness arising from vitamin-A deficiency, instead of having to rely on the therapeutic test.

One aspect of night-blindness that recurs frequently in the literature is the psychological factor. It is of interest that the family tree Cunier established in 1838 centred around the case of a recruit who complained of night-blindness and was regarded as a malingerer. Malingering was also suspected in the Boer War and still more in the last war, though some writers believed night-blindness to be a genuine psychopathic condition. The paper by Wittkower, Rodger, Scott, and Semeonoff in the present and in last week's issues of the *Journal* stresses the psychopathological aspect. It is possible that the novelty of black-out conditions might produce a psychological night-blindness in psychopathic individuals, but there is no evidence that such people form any considerable proportion of the night-blind population. In any case it is well to remember that night-blindness is a symptom of a wide range of conditions centring round organic disease of the retina and choroid, and around anomalies in the metabolism of visual purple arising from either local, general, or genetic factors.

CHEMOTHERAPY OF PLAGUE

The sulphonamide drugs have now been tried in the vast majority of bacterial infections, with rather varying success. The striking results obtained with coccal infections have, however, tended to obscure to some extent the fact that other diseases, such as those due to Pasteurellas, yield to treatment with sulphonamides. Preliminary observations by Buttle and his colleagues¹ had shown that sulphanilamide had a slight but temporary effect on infections due to *Pasteurella pseudotuberculosis* and *Past. septica* in mice, while Levaditi and Reinie² obtained similar results in mice and hens against *Past. avicida* when sulphanilamide and certain other derivatives were employed. More remarkable results were obtained in 1938 by Carman³ in the treatment of bubonic plague in East Africa. After nine patients had all died, prontosil soluble in the form of intramuscular injections of 2.5 or 5.0 c.cm. twice daily for four or five days cured three out of six patients. Vine,⁴ in a small epidemic in the Nilgiris in Southern India, also reported that three patients treated with prontosil recovered. In 1939 Schutze,⁵ Durand,⁶ and Girard and Girard⁷ all demonstrated that the sulphonamides exhibit considerable activity against *Past. pestis* in rodents. Schutze found that, when sulphapyridine, soluseptasine, and a diaminodiphenylsulphone glucose compound were given to mice and rats by subcutaneous injection or by administration in the food and drink, sulphapyridine proved the most efficient drug in both mice and rats, soluseptasine protected rats but not mice,

while for reasons which are obscure the sulphone compound was efficient in mice but not in rats.

Durand gave sulphapyridine, 2 mg. per gramme of body weight, to mice in their food for five or six days before and for from six to seventeen days after infection. Mice resisted at least 10,000 plague bacilli and on recovery were immune; if from 20,000 to 300,000 organisms were injected the mice died, but their tissues were sterile at death. Girard and Girard showed that mice receiving 100 mg. of sulphapyridine in their food in the space of six hours were as resistant as those given 0.3 c.cm. of immune serum. Guinea-pigs receiving from 120 to 300 mg. of sulphapyridine a day for from five to seventeen days resisted *Past. pestis* rubbed on the scarified skin: some guinea-pigs were cured even when treatment was delayed for two days after infection. Sulphathiazole, according to Sokhey and Dikshit,⁹ is even more active than sulphapyridine in curing mice. Doses of 40 mg. twice a day for ten days protected mice even when treatment was begun up to seventy-two hours after the infecting doses. Sulphathiazole they regarded as being as efficient as a potent antiplague serum.

Further successes in the treatment of plague in man have now been recorded. Moreau⁹ cured two cases of bubonic plague with a mixture of sulphanilamide and serum. Chopra and his colleagues¹⁰ obtained success in the case of a small girl of 6 who, in addition to having a bubo, developed bronchopneumonia: a total of 31.5 grammes of sulphapyridine was given. The most remarkable series of cases, however, is that reported by Wagle and others,¹¹ as the result of an epidemic in Bihar. Eighty-two patients who served as controls were treated with iodine intravenously; forty-five (or 52.4%) died. Of seventy patients given antiplague serum twenty (or 28.5%) died; of fifty-three given sulphapyridine thirteen (or 24.5%), and of thirty-two treated with sulphathiazole only five (or 15.6%). If patients with septicaemia at the beginning of treatment are considered, 95.0% of the controls died, as did 60.6% of those given antiplague serum, while of those given sulphapyridine and sulphathiazole 43.3% and 41.8% died. Although six patients with pneumonic plague all died, one was kept alive for eleven days. Larger doses might possibly have yielded a cure. These results open up a new chapter in the chemotherapy of plague.

RESULTS OF PLASTIC SURGERY FILMED

A film in technicolour illustrating the results of plastic surgery in war injuries has been produced under the auspices of the Ministry of Information on behalf of the Ministry of Health. It is intended to accompany and supplement a lecture which a delegate from the British Government will deliver at a number of medical conferences in the United States. The film, which is a speaking one, makes no attempt to give instruction in the technique of plastic surgery; it is merely an illustration of successful cases, a kind of "clinical meeting" recorded by the cinematograph camera. The commentary begins by describing the Emergency Medical Service with its institution of specialist centres in various parts of the country, their medical and surgical teams, and the patients drawn from members of the fighting Forces, the Merchant Navy, and the civil defence services, as well as persons injured in air raids. It is emphasized that ordinary surgical treatment is not thought to be sufficient, and that rehabilitation is the end in view. How successfully this is accomplished is proved by a number of cases from the plastic surgery centre in the

South of England, where very satisfactory results of grafting and repair have been achieved even in cases of great disfigurement and destruction of facial and other tissue. Training in a new occupation if the previous one can no longer be followed is included. One of the cases shown is that of a woman dancer who, when a London dance hall was struck, had hundreds of minute pieces of glass blown into her back; by patient treatment the worst of the damage was repaired. Another case was that of a woman doctor so injured in an air raid as to be unrecognizable when taken into her own hospital. Sixty pieces of glass were removed from the temporal, mandibular, and upper neck areas. In some cases artificial eyes were fitted, and—on the film at least—the casual observer might be deceived and not notice that the subject of the portrait had lost an eye. The film admirably suggests not only the skill of the plastic surgeon but the co-operation that must be required of the patient. It will show American audiences what is being accomplished in this country in the way of skin-grafting and other procedures.

AUTUMN HEALTH CAMPAIGN

So that every possible precaution against illness may be taken during autumn and winter the Minister of Health has decided, in collaboration with the Central Council for Health Education, to intensify the health education activities of the Department and the Central Council. In particular, efforts are being made to secure the co-operation of the public in reducing the spread of diseases caused by droplet infection—for example, influenza and the common cold—as well as diphtheria, measles, whooping-cough, cerebrospinal fever, and tuberculosis. Influenza and the common cold alone are responsible in normal times for between 30% and 40% of the working hours lost in industry. This special campaign was opened by the Chief Medical Officer, Sir Wilson Jameson, at his Press conference on October 1. Showcards and posters will be exhibited in buses, trams, and underground trains, at main-line railway stations, and in chain stores and the vestibules of cinemas, during the period up to the middle of March next; they will also, with the consent of the Ministry of Labour, be displayed in factories. The Minister of Health has asked local authorities to forward this campaign of health publicity by all means in their power. Copies of a sound-film made by the Central Council for Health Education to illustrate the dangers of unguarded coughing and sneezing are now available in the council's own film library, Tavistock House, Tavistock Square, W.C.1, or at the Ministry of Information's central film library, Imperial Institute, S.W.7, on free loan to approved borrowers for non-theatrical showing; and another film on the same subject may be added to the library at a later date. A three-weeks display of posters on droplet infection begin on October 25 in the windows of nearly 1,500 stores and gas and electricity undertakings throughout the country.

The following cable has been received at the headquarters of the British Medical Association from Dr. W. E. McCulloch, honorary secretary of the Jamaica Branch: "Your oldest Oversea Branch in annual meeting assembles. We send the parent body warmest greetings. We send you sympathy in your grievous losses, admiration and congratulation on the magnificent work of the profession in these times, and loyalty to what you stand for, envious of your position in the front line. We wish more and more Good Crosses to you all.—McCULLOCH."

"TO MATCH THE MEN"

*An Address at the Opening of the Winter Session of the
London School of Medicine for Women at Exeter*

BY

SIR ROBERT HUTCHISON, Bt., M.D.

When I first received the kind invitation of your council to address you to-day I confess I had some hesitation in accepting, and that for various reasons. In the first place it is probable that everything that can be said with profit on such an occasion as this has been said already, so "What shall I sing when all is sung and every tale is told?" as the poet plaintively asked. I hold, moreover, that there is too much talk in these days which does not lead to any result in action, and agree rather with Carlyle's doctrine of silence. Then again, it seems to be thought necessary by some at least of those who have addressed you in former years to choose a subject suited to women students and doctors as such. I have noticed, by the way, in some of these discourses a slightly apologetic note, almost as if women doctors might be compared, as Dr. Johnson compared women preachers, to a dog standing on its hind legs. "One did not wonder," he said, "that it was not done well but rather that it was done at all." Others, again, are rather over-congratulatory in tone, and insinuate, if they do not state, that the coming of women in large numbers into our profession has been of great advantage to it, and that on the whole women as doctors are better than men. But for my own part I think it is unwise to generalize about the differences between the sexes. As doctors at least I think they are much of a muckness, and I agree with that wise woman Mrs Poyer when she said: "I don't deny the women are foolish! God Almighty made 'em to match the men." My own experience, for what it is worth, has been that a woman doctor is like the little girl who had a curl right in the middle of her forehead: when she is good she is very very good, and when she is bad she is horrid—even horrid—than a bad man doctor.

But having weighed these objections, what finally determined me to fall in with the wish of the council was the reflection that, after all, it is up to us who have nearly run the professional race and are about to begin the descent into the dark valley to give to you to whom we are handing on the torch a word or two of cheer and, if it may be, of counsel. So here I am.

Let me begin, then, by congratulating you on your choice of the London School of Medicine for Women as your place of study. I do not do so as a mere empty compliment to this school, for it needs no flattery, nor for the reason that you can get as good a medical education here as anywhere, true though that is, but because it is a women's school to which men students are not admitted. You will gather from this, and rightly, that I am no friend to co-education, especially during the years of adolescence. Nymphs and shepherds may play together, but if they work together there is apt to be a good deal of time lost in dalliance. It is for the same reason that I do not favour the admission of women to men's schools: they are a disturbing element. You will call this, I know, a Victorian attitude, and perhaps it is, but it is rash to assume that the Victorians were always wrong.

Further, I think you have more opportunity of social and athletic activities, which are such an important ingredient of the student life in a school such as this, than if you are one of a small minority of women at a mixed school.

On Choosing Medicine

Be all that as it may, you are here to qualify for the medical profession, and one cannot help asking why you want to be doctors, for on your motives will depend to a considerable extent the spirit in which you work and the success you attain. I daresay a small number of you have been actuated by the loftiest motives, humanitarian or religious, by a love of mankind, or a desire to be doing the

work of the Master, and happy are those who have this crusading spirit. It is of such stuff that the best medical missionaries are made. Another small minority, no doubt, are at the opposite pole: you wanted freedom and a job of some sort, and thought medicine as good as any other. I am afraid that spirit won't carry you very far, but of course you may fall in love with your profession as you go on. Then some of you may have had a natural leaning to medicine for family reasons: your father or other near relative perhaps is a doctor. That, of course, may be a warning as much as an inducement, but for a son or daughter to follow the father's profession is as great a testimonial to that profession as a second marriage is to matrimony. A majority, probably, wished to take up some profession and thought medicine would be both interesting in itself and give opportunities for those personal contacts and relationships which specially appeal to women, besides being—as women's work goes—comparatively well paid. On the whole these are good reasons and reasons that will wear well. Lastly, there may be some who could not give any reason for their choice: they just felt in their bones that they would like to be doctors and that was all there was to it. Whether this argues a natural bent for our art I do not know, but I like to think so, for it is what made me become a doctor myself. I sometimes was tempted to regret my choice when I was doing the pre-clinical subjects, but—and this may encourage some of you with similar doubts—as soon as I got into contact with patients all misgivings vanished.

But from whatever motive you have taken up the study of medicine you naturally want to succeed. And that raises the question: What is success? Those of you who are just beginning will think of it in terms of getting through examinations, and you are right, for that is your immediate business and it is well to take short views. I am not going to say anything on the threadbare subject of examinations. They are a necessary nuisance, but you must not allow yourselves to be hag-ridden by them, as women students are apt to be even more than men. Try to regard them as sporting events, and don't take an occasional failure too tragically. Above all, don't think that examiners are ogres who would rather fail you than not; it is really quite unjust to the poor creatures.

Those of you, on the other hand, who have put examinations behind you will be thinking in terms of professional success and naturally look farther ahead. Let me advise you not to aim too high. The big prizes in our profession are only for the few, and they do not always bring much happiness when gained. "Seekest thou great things? Seek them not," as the wise man said. If you have earned enough for your needs and been able to put a little aside for your old age, and if, at the same time, you have won the esteem of your colleagues and the affection of your patients, you have done well enough, and that measure of success should be within the reach of most of you.

On Studying Medicine

But how is success, whether in examinations or afterwards, to be attained? Your share in attaining it can only be by hard work, for work, as Osler said, is the master word in medicine. You must therefore live the dedicated life, eschewing many amusements and distractions and concentrating on your work with singleness of purpose. At the outset you may feel rather appalled by the number of subjects you have to study. I sympathize with you in that, but I am not going to discuss the medical curriculum any more than examinations. We all regard it as a sort of chronic disease for which everyone has a different remedy. For my own part I should like either to treat it medically by a process of slimming, or to submit it to an operation for which the only instrument I should require would be a large sharp pruning-knife. Pending such treatment you must make the best of the curriculum as it is, and you will not be overwhelmed by it if you work steadily, unflinching and unrelenting, and taking each subject as it comes.

But you must know how to work. Medicine is an art even more than a science, and as most of you probably

learn better through the eye than through the ear, I should advise you to read chiefly in the book of Nature—in the laboratories, dissecting-room, and wards. You must, of course, attend the lectures prescribed for you, but don't consider them a waste of time. I am one of those who still think that the spoken word is better as a vehicle of instruction than the printed page unless the lecturer is totally unfit for his or her job. To get real benefit from a lecture, however, you must take notes, which you can expand afterwards with advantage. Note-taking not only helps the memory but it compels attention and will prevent a dull lecture from being boring.

I have said that most of your reading should be in the book of Nature, but of course textbooks have their uses too. I regret that most of them are such solid slabs of dullness. This makes it impossible to read them straight through, and there is no use attempting it. The proper way to read your textbooks is in connexion with the parts you are dissecting, your practical work in the labs, or, later, with the cases you see in the ward and out-patient room. I would suggest to you also that the best way to read with concentration is not against a background of noise produced by the radio, as seems to be a common habit among students to-day. Avoid above all things becoming the slaves of textbooks so that you can almost repeat chunks of them by heart. That produces the gramophone type of mind, useful enough sometimes in examinations, but apt to let you down in practice, for it means that you only have your knowledge indexed one way. It is quite possible, remember, to be able to give an accurate systematic description of a disease and yet to be quite incapable of recognizing it when you see it.

Further, you must not only acquire knowledge, you must digest it before it is any real use to you. Lose no opportunity, then, of talking over your work with your fellow students, and of joining in discussions and debates at student societies.

At this point I think I hear some anxious parent say: "With all this, is there not a danger of my daughter being overworked?" There is no use denying that such a danger exists, and it is greater, I think, in women students than in men because women are more conscientious. The same is true in practice. Women are more apt to let their work get on top of them and never to have it out of their minds. It is this, I think, combined with sketchy, irregular meals that accounts for the appearance of strain, the absence of the look of leisure, so often seen in the faces of professional women. Worry also plays a part—for women on the whole are greater "worriers" than men—worry about examinations as students and about patients later on.

I do not say that overwork alone has often serious consequences to health, but it is apt to engender staleness. This is only to be avoided by the introduction of system into your work and your life, by attention to exercise, sleep, meals, and a sufficiency of holidays, and by the cultivation of hobbies and tastes outside medicine. Above all, don't try to combine a social life and a student one. It can't be done. You cannot dance all the night and work properly next day.

On Getting Experience

And now a word to the recently qualified. You are entering our profession at a difficult time, when the future is obscure, "planning" much in the air, and the conditions in which you will have to practise uncertain. I should advise you not to worry about these things. Whatever happens there will always be plenty of opportunity for medical work, for however Demos may treat his priests his interest in his own physical welfare will always ensure that he has enough doctors and that they are reasonably well treated. You are at the most important period of your career when your real education begins, for it is now that you have to undertake personal responsibility for patients, and nothing educates like responsibility. The first two years after qualification are therefore most precious, and you should use them in getting practical experience in resident posts or as a locumtenent. Let me urge you not to be too high and mighty in applying for posts; not too

demanding, not too mercenary. You should be glad at first to work for your keep; you are probably not worth more. Don't let your first inquiry about every post be: How long holidays do I get? How often do I get a weekend off? Can I keep a car? (At that stage in your career you have no right to have a car at all.) But rather: How much experience am I likely to get, and what chance have I of doing things on my own responsibility? Not long ago I read in a medical journal of a young man who had applied for a post as house-physician at a provincial hospital and had been appointed, but on being told that he would be expected to give anaesthetics, if called upon, in addition to his regular duties he threw up the post. This action was applauded by the writer of the article, but for my own part I think the young man was a fool. If he had had the root of the matter in him he would have been glad to give anaesthetics, to pull teeth, to conduct a delivery, or to do any other odd jobs that came his way for the sake of that inestimable reward—experience. Leave it to domestics to say "I was not engaged to do that!"

Applicants for resident posts are usually required to produce testimonials and to appear at an interview. I attach little importance to testimonials, but the interview is of great importance, and it is essential that you should make a good impression. Be neither over-confident nor too diffident in manner. As regards appearance, it is not for me, of course, a mere man, to give you hints on dress, but it is only right to tell you, as one who has sat on many selection committees, that quite small things—a little too much make-up or the tilt of a hat, for instance—may imperil your chances, while if you paint your nails you are infallibly and rightly damned. In the matter of dress I often wish that women doctors wore a uniform: I am sure it would increase the confidence of their patients. Men doctors have set a bad example in this. Almost down to the last war the top-hat and frock-coat were *de rigueur*; now men doctors dress anyhow. The motor car, they say, is to be blamed, as it is for the loss of so many other of the dignified things in life, but the woman doctor has not that excuse. So you of the rising generation might think about it.

The Wide Choice

While passing examinations and getting experience you will be making up your mind as to your permanent work, and fortunately you have a wide choice. As I said before, few can aim at the so-called higher walks of the profession: but please don't talk, as I have heard a young woman doing, of being therefore obliged to "drift into general practice," for that, after all, is the most responsible branch of medical work and no one is too good for it. But general practice is hard work and many women cannot stand the strain of it. Many also shirk the responsibility or lack the initiative which it entails. On the other hand, women have many advantages as general practitioners. They are conscientious—sometimes too much so—and they ought to have common sense, perhaps the most valuable quality a practitioner can possess; for women, being responsible for the carrying on of the race, have always had to have their feet more firmly planted on Mother Earth than men. Intuition, too, is supposed to be a feminine characteristic, and intuition is the basis of that useful quality in practice—clinical instinct. Tact is another gift which you are said to possess in greater degree than men, and certainly general practice offers ample scope for its exercise. I think it is a mistake, however, to believe that women are more gentle in their handling of patients than men; indeed, I am not sure that the reverse is not the truth. Remember always that a "patient" and a "case" are not the same thing, and if your zeal to investigate the "case" do not forget that the "patient" is a human being.

Apart from general practice, there are now many posts in the public health services which are specially suited to women, for they mean fixed hours, limited personal responsibility, a regular salary, and a pension. They are not exciting or adventurous, but they are useful and safe. Some of you, again, may decide to go abroad—to India, for example, where there is a great sphere for women's work.

Research will probably appeal to only a few. There is no reason why women should not do great work in research, as the example of Madame Curie and others shows, but it is unwise to take it up unless you feel a real call, and it is often a blind-alley occupation.

There is one important respect in which the after-careers of men and women doctors differ, and that is in the effect upon them of marriage. Marriage is a great help to a man *qua* doctor; in a woman doctor it is apt to be a hindrance. Not always, of course, but it requires unusual strength and energy for a woman to run *matrimonium* and a profession in double harness, for matrimony is really a full-time job. It sounds very nice for a husband and wife both to be engaged in practice, perhaps as partners, but I don't think it often works. A man, after a harassing day, does not want to come home to talk shop to an equally tired wife. He wants to find someone with "a heart at leisure from itself to soothe and sympathize," and that is the woman's part. There are, of course, some part-time paid posts which a married woman doctor can fill—and perhaps all the better for her being married—but the rough-and-tumble of general practice is another matter.

What proportion of you will marry I do not know. I have seen it stated at 30%, but I should have expected it to be higher. Nor do I know how this proportion compares with that for non-professional women. I suspect, however, that preoccupation with professional work lessens a woman's power to please as well as her abstract desire for marriage. But, it may be said, if this is true there is at least a one in three chance that a woman's medical education has been wasted. But that does not follow. The study of medicine is a liberal education, and medical women make excellent wives, while their qualification is always a second string to their bow. There is therefore no real waste.

And now, having come to the end of my advice, I find it difficult to give a title to this address. Perhaps I cannot do better than use Mrs. Poyser's phrase, "to match the men," for it implies what I have wished to convey—that doctors, whether men or women, are much alike, and where unlike they are complementary to one another. Let me, therefore, as a final admonition and in no spirit of paradox, urge you, both as students and afterwards, to "quit you like men."

AIR RAIDS AND THE CHILD

BY

W. E. R. MONS, M.R.C.S., L.R.C.P.

Assistant School Medical Officer; Psychologist to Hostels for Difficult Children

While heartily condemning the habit of publishing premature conclusions based on relatively small experimental material, I feel I am justified by circumstances in making this small contribution to the evacuation problem now, instead of presenting the ultimate findings when the problem has ceased to exist.

During the past months thousands of evacuated children have returned to their homes in the danger zones, the parental attitude being usually expressed in the sentiments: "If the raids should start again the children can soon be evacuated once more." It seems appropriate, therefore, to remind parents that exposure to even a single "harmless" air raid can do great damage to a child's psyche be he ever so "normal" and "fearless" on the surface.

Miss A. T. Alcock, in an address at the Tavistock Clinic on was strain in children (*Journal*, January 25, p. 124), laid stress on the "difficult evacuated children" in whom the "principal disturbance was due to a physical agency, such as bombing." She pointed out that these "seemed to react much more in the way of unruly behaviour," and that "some who had been bombed were unable to perform ordinary school work." The Conference of the National Association of Maternity and Child Welfare Centres and the National Association of Probation Officers, reported under the heading "Prevention of Juvenile Delinquency" (July 12, p. 56), does not appear to have discussed the problem of the "bombed" child in particular. Dr. John D.

Sutherland, in his excellent "Survey of 100 Cases of War Neuroses" (September 13, p. 365), does not mention the subject either, while rightly pointing to the general principle that "war neuroses are essentially the neuroses in real war."

There are reasons to believe, however, that the child who has been exposed to the experience of one or more air raids is in a class by itself.* "Air-raid shock" is not a neurosis in the true sense. It does not affect only those with a strong predisposition, as in the case of the war neuroses, though it is easy to discover such predispositions in a large percentage of the children. The fact that neither personal nor family history, nor yet the previous school report, reveals the slightest trace of abnormality, and that the children show no neurotic tendencies in the Rorschach test, should serve to separate them from those in whom "air-raid shock" is superimposed on some previous weakness.

Behaviour of the "Bombed" Child

Previously good and intelligent children become suddenly obstreperous, destructive, mischievous, lazy, truant from school, and, in short, unmanageable in the billet to which they have been evacuated. In some cases the teacher of the new school expresses doubt about the pupil's mental normality where the previous report had stated him to be of scholarship standard. These children reveal as the foremost symptom a strange inability to occupy themselves in their free time. They are at a loss to know what to do with themselves, and seem to fear the responsibility of making any decision. They do not know what they want, and, in consequence, try to amuse themselves with one thing after another in rapid succession without being able to stick at anything for more than a few minutes. The result is, quite naturally, that with the exhaustion of the stock of permissible entertainment they get into mischief. Nor do they show any greater perseverance in these enterprises, and the child is merely a nuisance to himself and all others. It is the behaviour of deep resentment against the adults who have failed to provide that security and protection which is every child's birthright: the collapse of all the values which education had carefully built up so far. Death has become a personal problem, and parental authority is no longer a safe shield against this direct threat of extinction.

All this is common coin to those who have had to deal with evacuees. But it does not seem to be commonly known that the raid-shocked child reveals itself as a clinical entity in the Rorschach test in about 65% of cases. The exact nature of this reaction will form the subject of a special paper when more material has been collected. At present our observations are based on twenty-three tests on children who have been exposed to air raids and been sent to our hostels† as "difficult," and on thirty-two controls of similar ages at the same hostel who were evacuated before the raids.

It must be clearly stated at the outset that the Rorschach reaction in question is not pathognomonic in the clinical sense; it occurs also in other conditions and occasionally in the normal subject. The Rorschach test gives essentially a personality picture, and it would be unscientific to draw conclusions upon the effect of a temporary extraneous influence from a single record in the absence of any previous one. The reaction consists of the response "fire" (or its equivalent: "explosion," "sun," etc.) to the red at the bottom of Card II. To those who are working with this test this may seem banal, but the following figures are suggestive:

Boys exposed to bombing (Plymouth and Bristol 14, London 9)					23
Positive reaction	15
Percentage with positive reaction, 65					
Not exposed to bombing ("controls")					32
Positive reaction	6
Percentage with positive reaction, 18.7					

The analysis of the records of the first group shows that the positive reaction is given by boys who are showing little or no neurotic trend. This is partly due to the fact that the neurotic reacts usually in a specific way to the red in Card II, the neurotic reaction swamping, so to speak, the trend of the air-raid shock. Of the eight boys of the first group who failed to give the

* Compare also Mr. Tom Harrison's "Obscure Nervous Effects of Air Raids" (April 12, p. 573).

† The ages of these boys range from 9 to 14, the reason for their admission from "unmanageable" to "probation" cases.

expected response, four answered with "blood" and gave an abnormal record showing strong pre-existing tendencies. This explains, also, why so few of the men with war neuroses among soldiers returned from France (whom I had the privilege of examining at a Military Emergency Hospital last year) gave the reaction, for they were, in the words of Sutherland, merely "neuroses in war."

Normal Child's Unconscious Reaction to Bombing

We are, therefore, dealing with an upset not so much of an abnormal as of an essentially normal personality in these children, and one that is different from that due to the exigencies of evacuation. It need hardly be mentioned that any air-raid shock supervening upon a neurotic or otherwise abnormal personality will produce more severe symptoms than in a "normal" one. The child's reaction to the raid or raids is essentially unconscious. In the majority of cases he tends to make light of his experiences, denies having been frightened, and behaves in that casual manner characteristic of an adult. Nor is the severity of experience any criterion. In one case the boy had (according to his own statement) slept through the whole raid in his bed; but the realization next day of the nearness of death served sufficiently as a shock to upset him. In another case the experience of a mine explosion in his neighbourhood acted as the cause. In none of these cases was there a "war neurosis" in the true sense; nor did the Rorschach test suggest such a diagnosis. The behaviour of the boy toward aircraft noises appeared quite rational, and only those with neurotic trends showed any flinching at sudden noises.

On the other hand these children are no longer what they used to be. It is obvious that the effects of their inner experiences appear much more clearly when the strain of an evacuation is added to them. What parents and teachers at home could not spot bursts out unmistakably when the child is among critical strangers. In the several thousand evacuated school children I had occasion to study, the difference between the "bombed" and the "un-bombed" child revealed itself blatantly on putting a few questions. It may be that the children from the Plymouth and Bristol dock area are of a tougher fibre than the London evacuees. But their inability to fit into billets, the excessive number of difficulties between hosts and children, the bad school reports, and the unruly behaviour of the majority of these children cannot be explained on those grounds alone. Most of the evacuated London children have almost to be fetched home by force; most of the Plymouth and Bristol evacuees want to return home. Among an adult world that has been shaken in its foundations the world of the parents offers still more security than that of strangers. For the child, as mentioned before, is not aware that it has been upset by the raid experience, or it would not return to the danger zone so readily.

The prognosis, in our at present limited experience, appears to be good for all cases not complicated by neurotic trends. Removed from the billet, where the problem of "what to do in my free time" creates the main trouble, they tend to become exemplary pupils in the hostel—actually a residential school. Psychotherapeutic interference is unnecessary, and the routine and the discipline of a happy life among other boys remove all strain in a short time. But as it is impossible to provide such schools for the thousands of children who may become sufferers from air-raid shock during the coming winter because their parents are too short-sighted to profit by the evacuation scheme, every effort should be made to enforce the scheme while there is yet time.

A. Lesser and L. R. Kaufman (*Surg. Gynec. Obstet.*, 1941, 73, 163) state that in 15 out of 132 patients operated on with a pre-operative diagnosis of acute appendicitis, the diagnosis was erroneous, the true condition being acute salpingo-oophoritis, acute inflammation of chest conditions, pleural or abdominal tuberculosis, pyelitis, mesenteric adenitis, and acute rheumatic fever. In the 15 cases the sedimentation rate was constantly elevated or high, whereas in more than 90 cases in which the diagnosis of acute appendicitis was confirmed the sedimentation rate was normal. These findings confirm the importance of the blood sedimentation rate in the diagnosis of acute appendicitis.

GALLANTRY IN CIVIL DEFENCE

A Supplement to the *London Gazette* dated October 17 announces the award of the M.B.E. (Civil Division) to Dr. DONALD MORTON DUNN, house officer, London Chest Hospital, and the B.E.M. (Civil Division) to Miss DAISY JEROME, probationer nurse, London Chest Hospital. The announcement reads as follows: "The London Chest Hospital was severely damaged by enemy action. There were heavy falls of masonry in one wing, and two elderly women, both seriously ill, were trapped. These and the patients of an adjacent ward, some of whom he had to carry single-handed, were taken to safety by Dr. Dunn. Nurse Jerome, who was injured while attending to a patient at the moment of the explosion, helped in the rescue work. Later she was knocked over and rendered unconscious for a short period, but on recovery she returned to the ward and continued to assist Dr. Dunn until all the patients were evacuated. Dr. Dunn and Nurse Jerome showed courage and great devotion to duty."

The names of Dr. Arthur Thomas Miles Myres, resident medical officer, London Chest Hospital, Dr. Gustav Sussman Norris, civil defence mobile unit, Islington, and Dr. Lewis Aubrey Westwood, medical officer in charge, London Chest Hospital, have been brought to notice for brave conduct in civil defence.

Local News

ENGLAND AND WALES

Post-war Hospital Policy

Speaking at Oxford at a meeting of the Regionalization Council of the Nuffield Provincial Hospitals Trust, Mr. W. M. Goodenough, chairman of the Trust, said that in both municipal and voluntary hospital circles the liveliest interest had been aroused by the statement on post-war hospital policy which was made on October 9 in the House of Commons by the Minister of Health. If he read this statement correctly it would appear that the Minister envisaged the development after the war of a comprehensive hospital service which would be available for all persons in need of treatment. That service was to be based on extended responsibilities to be laid on the public health authorities and on the development of the partnership between those authorities and the voluntary hospitals, which would be placed on a more regular footing than heretofore. This policy, he had no hesitation in saying, was one which both local authorities and voluntary hospitals would welcome and support with enthusiasm. Indeed, it was largely identical with that which the Nuffield Trust had endeavored to promote to the best of its ability. It was clearly based upon the complete reconciliation and the utilization to the best advantage of those bodies, both statutory and voluntary, on which the present hospital services depended. Mr. Goodenough believed that if full regard was given to all parties concerned, if, in fact, the idea of a "partnership," of which the Minister had so wisely spoken, was made a real one, the policy would be generally acclaimed and would find willing acceptance from all quarters. It was in this way that a truly national hospital policy would be achieved.

After "Coventry"

The heavy air raid on Coventry in the middle of last November gives the theme to the annual report of the medical officer of health, Dr. A. Massey. The number of casualties is not given. Drainage and water communications suffered much, and in view of the possibility of a typhoid outbreak the city lived "on the edge of a volcano" for a few weeks. Its escape was due to the immediate application of all preventive measures and the co-operation of good citizens. In the three weeks following the November raid 17,000 persons, or about 10% of the population remaining in the city, were immunized against typhoid by inoculation. Universal boiling of drinking water and milk and the chlorination of the public water supply were obvious preventive measures from the first. Conditions of severe raiding introduced urgent sanitation problems; measures for the disposal of excrement after heavy damage to sewers and drains

have been an important task of the sanitary inspectors and members of the city engineer's department. On the subject of shelters the medical officer of health says that so far early misgivings have proved unwarranted. After two winters of black-out conditions and shelter life the physical and mental health of the community, while not inviting complacency, has been maintained at a satisfactory level. A local scheme is in operation whereby medical and nursing attention is available at all the larger public shelters. The death rate in Coventry in 1940 was the highest since 1938, but the figure, of course, includes air-raid fatalities; without these it would presumably be round about the average for the last ten years. Coventry looks ahead and finds that the raid damage, which was to some extent in areas that would have been subject to slum clearance measures, has given the opportunity for post-war planning on healthy lines.

The Hospital for Sick Children

Some of the wards, fortunately empty, of the Hospital for Sick Children in Great Ormond Street suffered in an early air raid, the damage amounting to many thousands of pounds. The hospital, however, has continued its dual work as a casualty clearing station and a children's hospital. Urgent cases are still received and treated at the hospital, but all others have been transferred to the sector hospital at Hemel Hempstead, which, staffed by doctors and nurses from Great Ormond Street, has kept in being the tradition of the old hospital, now in its ninetieth year. The evacuation of children from London, however, has deprived many parents and doctors alike of the hospital out-patient facilities. It was felt that this deficiency could be met satisfactorily only by the establishment of out-patient clinics in the areas to which the children had been evacuated or to which they could conveniently be taken. Watford was chosen as the first centre, and, aided by the Peace Memorial Hospital there, the clinic has been a great success. In the annual report just issued the hospital chairman, Lord Southwood, states that notwithstanding many difficulties the year 1940 closed with a small surplus, and the rebuilding fund received many substantial gifts, with the result that the overdraft has been reduced by £41,000.

The Health of Brighton

Brighton as a restricted area has never endured such obscurity since it became a fashionable resort at the end of the eighteenth century, but it still houses a civilian population of 150,000, and the medical officer of health, Dr. Rutherford Cramb, in his annual report states that the general standard of health has been remarkably maintained. There is no evidence of deterioration in the standard of nutrition, nor has the morale of the people been undermined by enemy action. It is interesting to compare the vital statistics of Brighton for 1940, the first complete year of the war, with those for the comparable year of 1915. The birth rate in 1915 was 16.87; in 1940 it was 12.48, a considerable drop even on the figure for 1939. The death rate in 1915 was 16.20 and in 1940 it was 13.50, and the infant mortality rate for the two years was respectively 97 and 69 per 1,000 births. Measles became epidemic in 1940, but the type was mild, and the number of deaths out of 2,675 known cases was only 3. Considerable use was made of measles convalescent serum either to prevent or to attenuate an attack in contacts. The medical officer of health considers that so far as infectious diseases were concerned the year was weathered very well, especially having in mind the apprehension and anxiety with which the use of air-raid shelters was regarded. In speaking of the casualty services, which acquitted themselves well on the many occasions when they were demanded, the medical officer records his appreciation of the valuable work done by medical officers of the stationary and mobile first-aid posts and the personnel attached thereto during raids. All the members of the whole-time staff of the various departments, including the school medical service, continue to do tours of duty covering each twenty-four hours at the control centre for civil defence. They also act as designated medical officers, and are sent to give emergency treatment to casualties at the scene of the incident. In addition six private practitioners have volunteered their services for this important work, and also attend as incident medical officers. A note is made of scabious and verminous cases; 105 Brightonians and 118 evacuees were treated for scabies at the sanatorium. The position is not one of any

severity, but energetic measures are being taken to maintain the gradual improvement observed in the borough each year before the outbreak of war. The report embodies that of the school medical service, and some interesting figures are given as to the results of medical inspection and treatment of the several thousands of children evacuated to Brighton from London and Croydon. A clinic for these children was opened in the spring of 1940, at which 1,423 children made 4,588 attendances.

The Blinded in War

St. Dunstan's, which now has its war hospital and training centre at Church Stretton, is repeating in this war the service for the blinded which it first undertook in 1915. Up to the end of March it had received 101 blinded men and women, 86 of them from the Services or home defence organizations, and 15 civilians. Of those in the Services category 45 have recovered useful vision, enabling them to return to civil or military life, at least temporarily, and 41 remain at St. Dunstan's for appropriate treatment, training, and after-care. Of the civilians, a few have recovered some useful vision, but the majority have been transferred for hospital treatment to their local authorities or to the National Institute for the Blind. Sir Ian Fraser, chairman of the executive council, in the twenty-sixth annual report of St. Dunstan's, makes the comment that those who have been blinded in this war seem to have a more serious and thoughtful outlook than their equally afflicted predecessors a generation ago. "We thought we did pretty well when we came back from France or Flanders or Gallipoli and found our way around in a new world of darkness, but we have been surprised at the speed with which the new St. Dunstaners are learning to be blind. . . . They do not shuffle along with a tapping stick like the proverbial blind man of ancient times, but walk erect and fearlessly and try to look and behave as normally as possible." He adds that recovery of sight is impossible for many, but recovery from blindness is the rule. They learn to "see" their way about by touch, hearing, and smell, and by the sense of location and obstacle which soon develops. St. Dunstan's, in consultation with the Dominions and with the Viceroy of India, is planning for the care of Dominion and Indian blinded men, and in South Africa a nucleus of a training centre has been created for men of the Forces evacuated from the Middle East.

SCOTLAND

Post-war Hospital Policy in Scotland

Mr. James Johnston, Secretary of State for Scotland, on October 18 opened the Ayrshire Central County Hospital at Eglinton, Irvine, which, built at a cost of £400,000, is designed to treat in one section infectious diseases, tuberculosis, and venereal diseases, and in the other section maternity cases. Mr. Johnston declared that the aim of the Government in its plans for post-war hospital service was to ensure appropriate treatment for every person in need of it. The Government proposed to develop the hospital service in a kind of partnership among the various hospital authorities, and wished to see the greatest co-operation between voluntary hospitals and local government bodies. One question of special importance was the future of the new hospitals built for the E.M.S. and at present under the direct administration of the Department of Health. He thought that in Scotland these hospitals would bring to an end the shortage of hospital beds which had existed for many years. In the meantime much was being done to reduce waiting-lists. Under an arrangement agreed with the British Hospitals Association some months ago about 1,300 patients from the waiting-lists of voluntary hospitals had been treated in emergency hospital beds. Plans were being worked out, and for many parts of Scotland would be ready within the next few days, for the treatment of patients on waiting-lists who were suffering from gynaecological and ear, nose, and throat conditions. Mr. Johnston also referred to nurses' salaries, a question under consideration by the Committee of Inquiry into Scottish Nursing, of which Lord Craigmyre was chairman. Even before the committee reported the Government had promised an interim grant to pay higher salaries. It was hoped that this committee of inquiry would be the precursor of a Whitley Council for the nursing profession.

Polish Hospital in Edinburgh

On October 17 Lord Rosebery opened the Paderewski Hospital in Edinburgh in the presence of General Sikorski, Prime Minister of Poland. The hospital has been established in a building with eighty beds. It has examination wards, a radiographic department, and a dental clinic, all furnished with modern equipment; it also has the use of the operating theatre in the Western General Hospital, in whose grounds it is situated, and two surgical wards each containing twenty beds. The primary purpose of the Paderewski Hospital is to accommodate Polish civilians, members of the families of officers and men of the Polish Forces, and it is staffed for the most part by Polish doctors and nurses. Teaching facilities will be available for students of the Polish Faculty of Medicine, Edinburgh. Prof. Jurasz, Dean of the Faculty, spoke of the valuable help given to the project by friends in America, and thanked the University and Corporation of Edinburgh, the Public Health Department of the city, and the Department of Health for Scotland for their ready co-operation.

INDIA

Health Conditions in Northern India

A severe Indian famine and the measures taken to deal with it are described in the last report of the Punjab Public Health Department. An intense and prolonged famine visited the Hissar district, to the north-west of Delhi (population 900,000). In the early part of 1939 a nutritional investigation in the famine areas of Hissar showed that vitamin A was present in quite inadequate quantities in the diets of the families taken, and vitamins C and D were absent altogether. Arrangements were made for fresh vegetables to be available for distribution by relief workers, and all persons found with signs of A and D vitamin deficiency were treated with cod-liver oil. A rapid deterioration in the health of the district took place during the closing months of 1939, and scurvy made its appearance. The district was then divided into a series of fifty health circles, each in charge of a medical officer, and special treatment centres were established to which the acutely ill were evacuated. Arrangements were also made for regular visiting of sick in the villages. The most specific preventive measure adopted to check the development of deficiency disease was the introduction of germinated grain as a prophylactic and of the Indian gooseberry (*amla*) for the treatment of acute scurvy. Germinated wheat or millet was issued freely to the extent of one ounce twice a week to each individual, and by the middle of February, 1940, more than 200,000 were taking this protective food regularly. During the first six months of 1940 the number of deaths was 15,504, compared with 21,337 during the corresponding period of 1939, and there was a marked decline in admissions to hospital and treatment centres. The Director of Public Health thinks it justifiable to conclude that, thanks to the specific preventive measures introduced, the major epidemic and deficiency diseases have been brought under control, but lesser degrees of malnutrition were still prevalent in the middle of 1940, resistance to disease in general was low, and health conditions extremely unstable.

The Director of Public Health of the United Provinces has also issued a report for 1939. It records a great improvement in the cholera position. The number of deaths from cholera in that year was 27,732, as compared with over 70,000 the year before. Out of 442 towns in the Provinces, 278 were entirely free from cholera, and the deaths in 109 others did not exceed 10. A question considerably debated is that of prohibiting people who have not been inoculated against cholera from visiting the larger *melas* or fairs. It is pointed out that, although there is always some cholera in the United Provinces every year, there has almost always been a widespread epidemic in the years (about every fourth year) in which *melas* bringing together large gatherings of pilgrims have been held at Hardwar and Allahabad. The cause of the widespread epidemics is believed to be the importation of the disease from endemic areas of Bengal, Bihar, Orissa, and

other places. Of the other principal diseases, plague showed an increased mortality (21,662 deaths, as against 13,436), and the deaths from small-pox rose from 4,411 in 1938 to 10,205 in 1939. The greatest killing disease, however, is malaria, which was reported in epidemic form from sixteen districts, including 2,250 villages. Vigorous malaria investigations and anti-malaria schemes for rural areas are being pursued. The quinine and cinchona distributed during the year from public sources (without counting private purchases from chemists) amounted to 8,843 pounds. There is an improvement in infant mortality in the United Provinces, the figure being 139.45 per 1,000 births. There are now 317 maternity centres in the United Provinces. Excellent work is done by Red Cross workers in promoting maternity and child welfare.

Correspondence

Medical Education

SIR.—From the interesting correspondence on medical education it is evident that one great problem concerns the gap which is said to exist between physiology and clinical medicine. The suggestion was made that teachers of physiology should use clinical cases to demonstrate certain facts, but Prof. R. J. S. McDowall (October 11, p. 524) gave reasons why this method failed. A better plan, in my opinion, is to bring students into hospital during their third year. Some years ago I began this in the Birmingham Medical School, and now on Saturday mornings these students come to hospital and are taken for part of the time by a physician and for part by a surgeon. The students appear to be keenly interested, and no doubt feel some thrill in at last coming into contact with patients. Patients are seen in their normal setting; there is no embarrassment on either side; and patients can be shown who are too ill to be moved to the physiology department and yet are of great value in illustrating physiological facts.

To give a concrete example. A woman with congestive heart failure was shown to a class of about forty third-year students. They were asked to look at the patient and tell me what they observed. I was told that the patient was short of breath, was propped up, was cyanosed, and that the legs were swollen. They overlooked the distended jugular veins and the fact that she had a cough and some sputum which was slightly blood-stained. Some of the students were asked to count and describe the pulse. Pitting of the legs was produced, and the enlarged liver was demonstrated. Dyspnoea, the outstanding symptom, was then discussed. It was explained that dyspnoea was a subjective phenomenon, something the patient complained of, and what they noticed was that the breathing was hurried, rather deeper than usual but not forcible, and that the breathlessness was increased when the patient lay down or exerted herself. What is the cause of physiological dyspnoea? That led to a discussion of basal metabolism, the effect of exercise and of anaemia, and so to pathological dyspnoea, the kinds of anaemia, the reduction of vital capacity, the cause of cyanosis, and the application of this knowledge to explain why this particular patient was short of breath. Why were the legs swollen? How much fluid must be exuded before oedema is apparent? How does oedema in this case differ from that in a renal case? How is venous pressure estimated? What signs does the patient show of increased venous pressure? Why is the pressure raised in this patient? Finally we arrived at the fundamental problem of heart failure. What is the normal output of the heart at rest and on exertion? What do we mean by the cardiac reserve? Does the heart fail because of increased work or weakness of the muscle? If the latter, why did this patient's heart fail?

The students were asked to think things out for themselves as far as possible. Intelligent answers were obtained, and they were pleased to show off their knowledge of such things as basal metabolism, the normal output of the heart, the amount of reduced haemoglobin necessary for cyanosis to appear, and

so on. It interested them to see this knowledge used to explain what was happening inside a patient, and it was not difficult to show them the value of physiological facts which had no vital meaning for them until confronted with a patient.

The suggestion is frequently made that "applied physiology" should be taught during the clinical years. Applied physiology is a bastard subject. It implies that much of the physiology taught cannot be applied, and that therefore it is necessary to pick out certain things that are of practical value in clinical medicine. But if *human* physiology is taught all of it should be capable of being applied. There is no gap. Applied physiology is a great part of medicine and the right teacher of it is the physician. For example, if the physiologist teaches the normal regulation of the heart beat the physician will use the student's knowledge of this to explain the meaning of auricular fibrillation, extrasystoles, or heart-block. If the student has been taught the normal elaboration and secretion of bile the physician will build upon this to elucidate pathological jaundice. From the moment a student begins his medical clerking his physiological knowledge should be tested and expanded by the attempt to understand the physiological dysfunctions which every patient shows. There should be no need for the intrusion of an "applied physiologist" between the physiologist and the physician.

Systematic lectures on medicine, which it is now the fashion to decry, again afford an opportunity of bridging the gap. I consider that there is a place for systematic lectures, but I agree that they should not be compulsory. If a student cannot learn anything of value from them he should stay away and read his books instead. The function of the systematic lecture is not the repetition of textbook matter. It should be concerned not with details so much as with basic principles and major problems, with explaining "how" and "why." In a clinical lecture a patient provides the text. His history is discussed, signs and symptoms are elucidated, a diagnosis is arrived at, a prognosis formed, and treatment outlined, but all with special reference to the particular patient. We study the natural history of disease in an individual. We are concerned more with the art of practice than with the science. There is little time to discuss the physiological basis of symptoms and signs. It is difficult to see the wood for the trees. Some systematic lectures are required to supplement clinical lectures and textbooks. In what textbook, for instance, can a student find a clear account of the evolution of tuberculosis in a phthisical patient? But in a lecture we can begin with the fundamental experiments of Koch and so explain the primary infection of the Ghon's tubercle with its glandular response, the allergic phenomena of the secondary stage, the possible spread to other organs, the development of immunity, the appearance of the tuberculin reaction, and so on, to the reinfection and production of the localized adult type of lesion. However thoroughly a case of phthisis is studied in a clinical lecture understanding will not be complete without a knowledge of these basic principles and of the aetiological factors seen from a broad humanistic standpoint.

The study of textbooks would be greatly improved by rearranging museums. Museums should illustrate diseases and not be collections of isolated organs. A student reading about subacute infective endocarditis should be able to take his book to a section of the museum where he would find displayed a typical heart, flea-bitten kidneys, infarcted spleen, cerebral embolism; typical temperature charts; coloured photographs of patients with a café-au-lait complexion, purpuric rash, and Osler's nodes; charts showing age and sex incidence, the frequency of rheumatic and congenital lesions, and so on. How much better than reading at home, or in a museum where hearts are segregated in one corner and kidneys in another.—I am, etc.,

Birmingham, October 16.

W. H. WYNN.

Students and the Curriculum

SIR.—Discussion has recently appeared in your columns concerning the plans of the British Medical Student Association to produce a memorandum on teaching and curriculum for the Medical Planning Commission. A few words about the progress so far made would, therefore, appear of value.

In the first place, it is obviously desirable that such a memorandum should be based on as widely representative dis-

cussion as possible. Most of our efforts, therefore, have been directed towards publicizing B.M.S.A. among the rank and file of medical students. This is of primary importance, because if the memorandum is to be of maximum value every possible opinion must be ventilated and as many contributions as possible be made to the general fund. In particular, the co-operation of the great London schools is essential to success. The methods of publicity so far adopted have taken the form of articles in the medical press and student journals. In the near future we are planning the publication of a pamphlet, of which we hope to sell at least 2,000 copies. This will include material dealing with B.M.S.A., its history and plans, together with schemes for the organization of discussion on the memorandum.

We realize that it would be a mistake to attempt to "rush" the production of this memorandum. Such a project, to be worth while, must be a closely reasoned and detailed document. We consider that probably a year will be required before the final draft is completed.

B.M.S.A. has asked each school to appoint a representative who will deal with B.M.S.A. material and arrange meetings, debates, and discussions around the various points of the memorandum. Detailed results will be forwarded to the secretaries and correlated under the following section headings: (1) General problems affecting teaching and curriculum; (2) The first year; (3) The second and third years; (4) The final years. One or two preliminary reports are already to hand, and several schools, particularly in London, are actively co-operating.

B.M.S.A. is fortunate in having for its honorary president Prof. J. A. Ryle, while our vice-presidents include Mr. H. S. Souttar, F.R.C.S., Prof. Hugh Cairns, F.R.C.S., Sir John Boyd Orr, F.R.S., Sir John Stopford, F.R.S., Prof. Wood Jones, F.R.S., and Dr. J. Trueta. This indicates that leaders in various branches of our profession view with sympathy the attempts of students to formulate their ideals and ideas with regard to medicine and are prepared to assist. One of the main points of B.M.S.A.'s policy has been to encourage a closer co-operation between teachers and students, not only in purely academic affairs but in the practical everyday matters of hospital and university life. Such schemes operate with benefit in several medical schools. Provided co-operation is organized in a businesslike manner, with definite allocation of responsibility, this cannot fail to be of permanent value both to students and to teachers. We hope that teachers will contribute, from their knowledge and experience, to the students' discussion around the memorandum, and we appeal to students to enlist such support wherever possible.

B.M.S.A. is beginning to play an important part in medical student life. Medical students are realizing their duties to society, and we believe that their aspirations and plans can be most effectively fulfilled through the development of their own organization.—I am, etc.,

University Union, Manchester,

Student Association.

Voluntary Hospitals

SIR.—In reply to the comments on my letter in the *Journal* of September 27 (p. 456) it is difficult to understand how anyone of Dr. Goodhart's experience (October 18, p. 558) is unable to reconcile the apparently opposed statements made by Dr. Kenneth Watson and myself. I would rather believe that Dr. Goodhart is as aware as I am that no profound analysis is necessary to show that the statements are in sympathy with one another. I have no doubt that Dr. Watson (September 20, p. 419) refers to the omnipresent administrative hand, which is avoided by the medical officer so far as possible by the correct and proper filling in of forms, by punctual attendance to perfunctory duties, and by not demanding anything which might change established routine—be it for progress or not. Despite this, the medical superintendent regards all his medical officers as his clinical assistants. On the other hand, as I have already pointed out, skilled supervision of the medical officer's work is frequently inadequate. I need not mention again the detrimental effects of this state of affairs.

Dr. G. Osborne (October 18, p. 558) deplores that I did not mention the essentials regarding this matter of "atmosphere." I admit my letter was in no way comprehensive; and if he

refers to the fundamental reason for the lack of atmosphere in the municipal hospital I agree that I did not trace it to its source, but rather dealt with its effects. I might mention that even with the help of some colleagues, the best will in the world, and at the expense of some mental indigestion I was quite unable to disentangle a meaning from Dr. Osborne's second sentence—possibly a key one in his argument.

The main object of my letter was to point out that the absence of "atmosphere" in the municipal hospital is just one of the many unsatisfactory results of wrong arrangement of responsibility among medical personnel. By wrong arrangement I refer to the intervention of the medical superintendent in the system of responsibilities. I stressed the greater benefit for the patient, the junior medical man serving his apprenticeship, and the hospital itself of having adequately qualified specialists entirely responsible for their "firms" or departments. Recently I saw it said in the lay press that disciplined freedom is a condition of the highest life: the air it must breathe if it is to live at all, and equally the only atmosphere in which a nobler state of society can possibly arise. This is not irrelevant to my theme, for it is only in this atmosphere that the various departments of a large hospital can thrive. It is, in fact, the atmosphere which Sir Frederick Menzies has asked us to define, and that which the municipal hospital lacks.

The essential cause of its absence or the factor which inhibits its development in a municipal hospital, which Dr. Osborne seems to regret that I had omitted mention of, is the position of the medical superintendent in the scheme. But here there must be pause for thought. It is manifestly unfair to heap criticism on medical superintendents, whose fault is chiefly their position in the system, a position which expects of them more knowledge than they can possibly possess and gives them more power than they can fairly wield.

The erection of magnificent buildings, justly symbolizing progress in the lay and administrative mind, increasing the efficiency of the unit but little unless the essential reorganization and development of the medical and technical staff is complementary—and proceeds apace. It must be remembered that the medical superintendents have been the key men in the truly remarkable evolution of many of these hospitals—a change which now makes possible their comparison with the voluntary hospitals. But it is now apparent, and most clearly so in those hospitals which have reached the highest stage of their development, that the medical superintendent with his *verboten* in every department has ceased to be an impetus and has become an incubus on further essential progress.

It is therefore important that criticism should be dispassionate and come from those who sincerely hope to see the large municipal hospitals progress still further to reach the same standards as the voluntary hospitals. I believe that the municipal hospitals can never throw off the last link that joins them with the Poor Law institutions of the past and enjoy the same status as the voluntary hospitals until the powers of the superintendent are modified so that he becomes a lay administrator only, occupying a similar position to that of the house governor in voluntary hospitals. Such reorganization is, of course, impossible until the various departments are in the hands of men qualified to be entirely responsible for them. Incidentally, the position of the administrative chair as the unwelcome goal of the medical officer would then be taken by professional positions at the head of the clinical departments.

Such a change in the character of municipal hospitals would promote co-operation between the two hospital systems; it is clear that this condition is vitally necessary for the organization of a comprehensive post-war service which may have to meet the needs of the great majority of the population. If a system of reorganization comes into being, the smaller hospitals are bound to be most favourably influenced.—I am, etc.,

D. LANG STEVENSON.

Oct. 20.

The Mental Defective in the Army

SIR.—My article in the *Journal* of August 9 (p. 187) has given rise to much correspondence addressed to the Press or to myself. It may be useful to summarize the criticisms and the replies.

The recommendation that a mental age of 10 years was a critical level below which soldiers should be recommended for

discharge has met with the objection that it is too high. I now reaffirm the point I made originally—that in this war increased mechanization and speed make it most difficult for the higher-grade mental defective to become an efficient soldier. He cannot understand the mechanics, use, and maintenance of the complicated instruments of modern warfare, and cannot be relied upon to act on his own initiative as a modern soldier is rightly expected to do. On the other hand he is a useful labourer when under the orders of a tolerant yet firm N.C.O. For this reason I still insist that no man with a mental age under 12 is likely to make a really successful and reliable modern soldier. Moreover, this figure has to be raised in the case of certain highly technical units which require a higher standard of performance and therefore men with a higher mental age.

Dr. J. J. Mason points out (October 4, p. 490) that in his observation mental defectives remain calm during air raids, but it is important to note that he is referring to institution cases. My observation of cases under similar conditions agree with his. Their calmness is to be compared with that of many London children whose parents were able to arouse in them some feelings of confidence in spite of the bombing. How different is the plight of a defective, harassed by the enemy and trying to attack a post under orders he barely understands, or to make his way back to Dunkirk, knowing rightly that his safety depends upon his wits and that these fall seriously short of those of his comrades and of the enemy. A man in such a state is ripe for a mental breakdown. There can be no real comparison between mental defectives under bombardment in institutions and those on active service, for the reason that active service is not a protective environment.

Since my article was written "B sections" of pioneers have been established, and I have been invited to inspect some. "B sections" consist almost entirely of mental defectives transferred from combatant units because of military inefficiency. The men are doing excellent work of simple labouring type and are happy. Those to whom I spoke were previously unhappy because their inefficiency got them into constant friction with their officers. These "B sections" are able to use men of much lower mental grade than the labour corps which are to be partially militarized. They can employ stable men whose mental age is as low as 8 years. The retention in the Forces of men as simple as this depends, to my mind, entirely on the provision the Army makes for them. As a parallel, it is not difficult to see that men incapacitated by deafness or partially crippled could be used in the Army provided suitable occupations and environment for them were found. The same principle applies in the case of mental defectives.

Letters to your *Journal* have been mainly critical, and from school medical officers or medical officers of local mental deficiency authorities rather than from officers of the R.A.M.C. or psychiatric colleagues who wrote to me personally. Most of these personal letters endorsed the view I expressed. It is fortunate that notice is now being taken of an urgent problem which is closely linked with the efficiency of the Army and the happiness of its men.

Perhaps the most profitable consideration at the present time should be not the estimation of "critical mental ages" as such but the relation between the types of work which men are called upon to do and the minimum mental age of those who can perform the duties efficiently.—I am, etc.,

F. J. S. ESHW

Sheffield, Oct. 22.

Exposure to Tetryl and T.N.T.

SIR.—As an old-timer from the ranks of those who fought in the battle against T.N.T. poisoning in the last war (and who fondly hoped they had won) I have read with deep interest the illuminating article on "Clinical Manifestations of Tetryl and Trinitrotoluene" by Dr. J. Hilton and Dr. C. N. Swanwick (October 11, p. 509). Unfortunately I read it in bed and it played havoc with my night's repose. Are we really going through, all over again, the pathetic tale of T.N.T. symptoms, sicknesses, deaths, post-mortems? It would seem incredible had we not constantly before our eyes that other pathetic tale of all we had learnt and all we have forgotten. Truly we British have a genius for forgetting.

I have no desire to write at length on the subject. I merely wish to state that what we know as "T.N.T. poisoning" is a preventable disease, and to ask if there is no one who will take up the cudgels to see that it is prevented. Why should we have yellow-stained or cyanosed workers travelling in the trains and scaring their neighbours? Why should we have what Drs. Hilton and Swanston describe as "the irritating effect of the crystals on the nasal mucous membrane" or "the small amount of dust present in the atmosphere of all shops"? Why should we have "dermatitis," "cyanosis," "toxic gastritis," "toxic jaundice," "aplastic anaemia"? Why should we have deaths? These things can and should be prevented. They were eventually prevented in at least one factory, for which I can speak, in the last war. All the details and methods of prevention were compiled, at the request of the Ministry of Munitions, at the end of the war—and are now probably to be found only in the Imperial War Museum.

The one imperative necessity is whole-hearted co-operation of the management of the factory with the medical officers in charge. A good deal of expense and some inconvenience are involved, as is the ever-present threat of diminished output. But the harvest reaped in absence of illness and deaths, in happiness and easy recruitment of workers, and in surely and speedily soaring output is the rich reward of the doctors, the management, the overseers, the workers, and the welfare staff—of all who make up the courageous and inspiring "corps" which, when war is past and gone, we still affectionately call "The Factory."—I am, etc.,

Glasgow, Oct. 14.

ELIZABETH FRASER BUTLER.

SIR.—I was interested in the views of Drs. J. Hilton and C. N. Swanston (October 11, p. 509) on the subject of the toxicity of tetryl and trinitrotoluene. My experience showed that C.E. (tetryl) was a common cause of facial dermatitis lasting four or five days. Permanent removal of workers from C.E. was rarely necessary. T.N.T., on the other hand, less commonly caused skin troubles, but those cases seen were often severe and sometimes resulted in a chronic exfoliative generalized dermatitis.

I was surprised to hear of toxic jaundice and aplastic anaemia reappearing in ordnance factories. I never saw either of these complications in two years at an arsenal.

In order to try and minimize the incidence of these cases I suggest that copies of an article by Dr. A. L. Leigh Silver, entitled "The Treatment and Prevention of Industrial Diseases in Filling Factories," be made available to all medical officers employed in factories handling explosives. The article in question appeared in the *Journal of the R.A.M.C.* dated August, 1938.—I am, etc.,

Welling, Kent, Oct. 18.

H. G. HOWITT.

Treatment of Scabies

SIR.—In view of the prevalence of this disease at the present time and the very heavy pressure on all hospital beds it is obviously essential to obtain the speediest possible cure. I was therefore surprised to read Dr. J. B. Marshall's letter (October 18, p. 561) stating that the average duration of stay in hospital for a case of scabies, uncomplicated by impetigo, should be four and a half weeks.

In this town we have a county council hospital, where 343 cases of scabies have been treated during the past eleven months. Proscabin (benzyl benzoate) has been used in every case. At least 90% of those treated have been evacuated persons. As they come from all over the county it is not possible personally to follow up every case, but it is a safe assumption that in almost every one the householder would speedily proclaim a recurrence, and the patient would then be sent back here. In fact, there have been two returns, both from the same house, where it was subsequently discovered that the householder herself had scabies and had not been treated. The average stay in hospital of the uncomplicated cases has been about five days. Those complicated by impetigo seldom remain more than ten days.—I am, etc.,

Maidenhead, Oct. 19.

TIMOTHY MAURICE.

SIR.—Dr. P. B. Mumford (October 4, p. 492) comments on the various treatments for scabies which continue to appear

and on the questionable evidence upon which successes are sometimes claimed.

There seems little doubt that ordinary sulphur ointment (10% for adults, 5% for children) is still the most reliable remedy, provided it is correctly used over a limited period. Dr. A. M. H. Gray (February 8, p. 211) says: "Inefficient treatment may convert an active into a latent case, one in which the symptoms are relieved but the disease is not cured and remains infectious. It would therefore seem advisable to employ methods of proved efficacy rather than those in which it has not yet been possible to control the results experimentally." Many cases, however, are still being either under- or over-treated, with equally unsatisfactory results. Much of this haphazard and ineffective treatment could be avoided if patients clearly understood what they had to do. Verbal instruction is so often useless; it is much better to give the patient some kind of printed leaflet, such as skin out-patient departments use. On this the importance of simultaneous treatment of contacts can also be emphasized. The following is an example:

SCABIES

1. On the first night of treatment scrub the whole body thoroughly with soap, hot water, and nail brush (preferably soft soap).

2. Dry yourself and then rub the ointment well into the skin everywhere except the face and scalp.

3. Rub more ointment all over, as before, each morning and evening for the next three days, without removing the old ointment. Do not take a bath during this time, and use the same underclothes, night clothes, and sheets.

4. On the fourth morning take a hot bath and wash off the ointment. Put on clean underclothes.

5. All washable clothes used before and during the treatment should be boiled, or preferably disinfected, together with blankets and day clothing, at the nearest cleansing centre.

6. Do not expect all itching to stop immediately after the treatment. If it persists for more than one week, do not treat yourself again but return for further advice.

7. Watch all members of your family or household for any itching or spots on the skin and bring anyone so affected for examination. This is most important.

—I am, etc.,

London, W.1, Oct. 19.

E. W. PROSSER THOMAS.

Sulphonamides in Cerebrospinal Meningitis

SIR.—Referring to Dr. T. P. Edwards's modest protest (October 25, p. 595), I gladly offer my apology for failing to realize and to indicate clearly that Dr. Edwards was personally responsible for the treatment of all the Wrexham cases of cerebrospinal meningitis which reacted so well to sulphonamide therapy. These excellent results convince me more than ever that in this disease the patient owes quite as much to the skill and unremitting effort of the doctor in charge as to the chemotherapeutic potency of the drug employed.—I am, etc.,

London, W.1.

Testing Night Vision

SIR.—In the *Journal* of September 6 (p. 347) there appeared an article on testing night vision by Mr. N. Bishop Harman in which the author claimed that "the extended trial of the disk-spotting test shows that it can be of use in testing large numbers of people with comparative ease and with exactness." While appreciating the value of this latest contribution on an important subject, we feel that one or two observations are necessary.

The test described by Mr. Bishop Harman is of the "threshold" type, and therefore the subject should be fully or almost fully dark-adapted. Yet after stepping from the brilliant sunshine fifteen minutes was regarded as ample time for recovery and the tests were started. Since, however, twenty patients at a time were brought into the dark room, presumably it was only the first patient who was tested at a fifteen-minutes recovery time, the remainder having successively longer recovery times as each waited his turn. The greatest errors will have occurred with the first few patients of each batch tested (particularly on the days when there was brilliant sunshine), since there is no question, of course, that the eye is never fully adapted after fifteen minutes.

Regarding the ingenious use of a standard candle, we understand, however, that this may under varying conditions of draught, temperature, and humidity give rise to considerable errors in illumination.

If we may suggest it, the test should be described as a valuable rapid test for approximately testing night vision, but any conclusions arrived at on the assumption that the test is exact should be treated with some reserve.—I am, etc.,

Research Department,
The Crookes Laboratories, N.W.10, Oct. 13.

E. W. GODDING.

** We have referred this letter to Mr. Bishop Harman, whose reply follows.—ED., B.M.J.

SIR,—The points that arise in the letter of Mr. E. W. Godding regarding testing night vision are of interest and must certainly be considered. If I may say so, I think that it is inevitable that Mr. Godding, from the closeness of his work with the production of the precious vitamins, would think of this night-vision problem almost exclusively in terms of health. He will naturally suspect those with poor night vision to be deficient in healthy vitamins. But it is clear from the character of the 700 subjects put through my test, and whose records are charted, that all of them were as well equipped with every vitamin that human beings could be. The 200 children belonged to a first-class school in a most delightful part of the country. They were as fine and lively a lot of boys and girls as could be found. Indeed, their liveliness made a long-timed testing in the dark tiring to an elder. The Canadian soldiers were as stalwart and well-fed a group of men as could be collected anywhere. The "elders" were all well-to-do residents of the district. All the subjects, therefore, were without doubt in first-class health. The tests prove that night vision may vary as much as colour vision. The variations are in the natural make-up of the subject. Indeed, I have some evidence that defective night vision may be hereditary in a few cases.

The fifteen-minutes-time adaptation to the dark is questioned since the subjects came into the dark in groups, so some got more time than others. My tests were carried on through many days. Each day I checked the reaction with my own eyes, and since I am over a long way in the "elder" group and wear glasses, that was a severe check. I could always get my full range of 5 metres in five minutes, even when I came into the dark from the sunshine. In my experience fifteen minutes is ample time. Further, subjects who responded badly to the test were put back at the end of the waiting line of candidates to try if a longer time gave them better vision. That is shown in my paper regarding the school boys, who wanted to do better than they had done, but who after half an hour in the dark showed no change in their reaction.

The standard candle test was chosen because it is the most "standard." No electric light can be so certain in the exactness of its measure. We ophthalmic surgeons know that in the use of our convenient electric ophthalmoscopes. The candle box is so arranged that the conditions of draught and temperature (when, as is inevitable, the test is done in enclosed premises) are as uniform as can be. So far as humidity is concerned, I cannot think that this would affect the candle light unless the damp amounted to a mist or a fog, and I cannot think that any eye man would attempt such a test in a fog.

This disk-spotting test was arrived at after some other methods of testing night vision had been tried. That is stated in my first paper of April 26. These preliminary tests were made with medical colleagues, whose criticisms were helpful. In my opinion these experiences justify the conclusion "that the disk-spotting test can be of use in testing large numbers of people with comparative ease and with exactness." Perhaps I should have written, "and with as much exactness as any test of human reactions can be."—I am, etc.,

N. BISHOP HARMAN.

Edenbridge, Kent, Oct. 17.

The Increase of Tuberculosis

SIR,—There are now many records of increased incidence and death rate from tuberculosis and many theories as to why this increase has come upon us. May I remind you of the turning out from our sanatoria of a great many tuberculous persons at the beginning of the war to make room for the casualties which were then expected to occur—an expectation which, fortunately,

did not arise—and of a prediction which I made in your *Journal* of September 16, 1939 (p. 621). Perhaps you will allow me to quote from my letter the words of a famous surgeon: "Every tuberculous person turned forth is like a bomb thrown among the public." I spoke of "the unwitting power of spreading the infection to those about them" by the tuberculous, "a power much more evident in crowded and unaccustomed conditions than in the familiar state of pre-war society." Is it necessary to postulate anything else?—I am, etc.,

Cheam, Surrey, Oct. 21.

S. LYLE CUMMINS.

Diagnosis of Early Venereal Disease

SIR,—In view of the importance of the subject at the present time the following remarks may not be out of place.

It is a continual source of astonishment to me to find that the last twenty-four years have seen very little change in the attitude of the medical profession generally towards early syphilis. The importance of diagnosing syphilis microscopically before the Wassermann reaction is positive is not realized. At the risk of hearing the remark from the more knowledgeable, "Elementary, my dear Watson," may I say that genital sores in either sex should have a saline dressing applied, and the patients should then be referred to the nearest V.D. clinic or V.D. specialist for "dark-ground" examination of the exudate.

I think it is time someone protested against the practice of first dosing patients with sulphonamides and then referring them to V.D. clinics for diagnosis. The condition is thus disguised effectually both from a clinical and from a bacteriological point of view. Particularly in females, chronic gonorrhoea is difficult enough to diagnose without anyone throwing a spanner into the works, so to speak.—I am, etc.,

NOEL F. ROWSTRON.

Sunderland, Oct. 20.

Treatment of Haemorrhagic Disease of the Newborn

SIR,—The article by Dr. A. I. S. Macpherson and the letter by Dr. John J. Robb on the treatment of haemorrhagic disease of the newborn (September 27, p. 433, and October 11, p. 526) are of interest to every practitioner, because this is an emergency which anyone may meet with, and "something must be done at once" if only to pacify the parents of the infant. You were kind enough to publish two notes on this subject (*Journal*, December 22, 1939, p. 1218)—one from me—when its treatment by injections of paternal whole blood was being discussed in your columns, and since then it has been my fortune to treat seventeen cases (with one death), all in general practice.

At first I used 8 c.cm. of paternal whole blood with 2 c.cm. of warm saline injected into the infant's buttock, and repeated this in twelve or twenty-four hours. Later five cases received the two blood injections plus 2 c.cm. of haemoplastin, and the next three were given one injection of blood and two of haemoplastin. Five years ago I was called at 1 a.m. to a four-day-old infant which had passed blood by the bowel sufficient to soil its clothing and mattress, and appeared to be about to die. The father was a bus driver and could not be found. The mother had fainted, and the only help was a neighbour. Motivated by the idea of "doing something" than with much hope of saving life, I injected 2 c.cm. of colloidal calcium with oset (Glaxo), which happened to be in my bag, and 3 minims of adrenaline. Half an hour later the child was still alive, and the injections were repeated. No more haemorrhage occurred, and an injection of this calcium preparation was given daily for a week, and the child is perfectly well to-day. Since then I have met with seven cases, all of which have been treated with the same preparation. All have survived; the last case happened as recently as four weeks ago.

The only case in the series which ended fatally was treated with maternal whole blood and haemoplastin, and there is to be accord that the mother's blood is less effective than father's in the treatment of this condition.

Vitamin K deficiency may be the explanation of why infants bleed and others do not. It may also be the explanation of why some women fall easier victims to infection at confinement, and why maternal blood is of less value than the father's in controlling the alarming condition of haemorrhage in newborn.—I am, etc.,

Stockport, Oct. 17.

F. J. K.

Tenosynovitis of the Tendo Achillis

SIR.—I was interested to read Captain A. A. Williams's report of tenosynovitis of the tendo Achillis (September 13, p. 377). The assumption that it is caused by repeated minor traumata bears out my own observations.

At one time a group of some fifty men of a unit in my charge lived in a village about three miles from the general parade ground, the road in between being one long hill of varying gradients. Among these men tenosynovitis was a veritable scourge, as many as eight men being off duty at one time, while among the rest of the unit it was rare.

I think the explanation of this incidence lies in the fact that coming in to parade in the morning the men were usually hurrying, and consequently taking a long pace. Coming down hill this caused increased plantar flexion and an accentuation of the wrinkles at the back of their boots. These wrinkles coming at every step pressed on the tendo Achillis, giving repeated minor traumata. I have also found these cases frequently occur after short speed marches in which a long pace is taken, while they are rare after a route march of thirty miles.

I agree with the treatment, particularly the wearing of civilian shoes, but I would like to bring the following point to notice. This condition is recurrent, so I have the men put 2 oz. of castor-oil in each boot when they return to duty, taking care it gets well round the heel, and they wear the same sticky oily socks for three days. This makes an Army boot as soft as cloth-topped affairs of yester-years, and the condition seldom recurs.—I am, etc.,

J. E. SYMONDSON,
Captain, R.A.M.C.

Oct. 20

Türk Cells, Plasma Cells, and Premonocytes

SIR.—In 1898 Türk described his "irritation or stimulation form" as a non-granular mononuclear cell, found up to 4% in pathological blood usually containing a few myelocytes; it had a round eccentric nucleus and ample cytoplasm staining dull brown with triple stain, and the smallest was little larger than a lymphocyte. Ehrlich and others accepted it as a definite addition to the leucocytes. In 1901 Weil described as "plasma cell" an oval non-granular mononuclear leucocyte whose cytoplasm stained deeply with thionine. But Pappenheim showed that in this and other staining reactions it was indistinguishable from the Türk cell.

In 1899 Ranvier described branched cells with oval nuclei in the connective tissues. Mobile and phagocytic, in his opinion they were modified leucocytes and he named them "clasmato-cytes." Marchand confirmed their presence, particularly in the adventitia of vessels, and contending that they were of tissue origin (histioid) named them "adventitial cells." By intravital staining Goldmann showed that they readily take up pyrrhol blue, so that adventitial cells are sessile phagocytes. They take no part in forming connective-tissue fibrils, but under pathological conditions become rounded and free and resemble monocytes. Thus monocytes, unlike neutrophils, are present normally in the tissue spaces and are abundant in the sheaths of blood vessels, whence they wander to any neighbouring focus of disturbance. Again, by supravital staining with neutral red and Janus green it has been shown that continuous formation of monocytes is proceeding in the superficial lymph nodes of the rabbit with premonocytes, and monoblasts as intermediates between them and adventitial cells (Forkner, Claude E. J. *exp. Med.*, 1930, 52, 279). I reported premonocytes in films from two cases of glandular fever—suggesting that, under pathological conditions, formation of monocytes may occur as in the rabbit (*British Medical Journal*, 1931, 2, 825).

Finally Maximow introduced the term "polyblast" for cells of mononuclear type, which often abound in inflammatory conditions of the tissues. He considered that they are derived partly from blood lymphocytes and partly from adventitial cells, and that plasma cells are merely a variety of polyblast characteristic of non-suppurative inflammatory cell infiltration. Thus polyblasts are normal inhabitants of the tissue spaces and, owing to irritation, have been mobilized at certain centres where many undergo plasmoid change. Some of the latter, entering the blood stream, become rounded or oval with nuclei less eccentric and more efficient than when loafing in the tissues. Yet traces of the wheel nucleus of a tissue plasma cell still remain in

some of the smaller Türk cells, and foamy cytoplasm or perinuclear halo is common enough in the larger to suggest their origin.

In films from a healthy man I found two Türk cells in counting 2,500 leucocytes. Thus, though rare, they are present in normal blood; but in any ordinary count more than a single cell is pathological. Most acute febrile diseases show 1 to 2% in a few days, and it was doubtless in such cases that Türk discovered the cell. Measles and rubella show a remarkably high percentage, owing partly to leucopenia, on the third or fourth day of the rash—often reaching 5% in the former and 10% in the latter. Incidentally, this excludes scarlet fever, indicating measles when Türk cells are not over 5% and rubella when not under 8%. Clearly the film shows twice as many young recruits in rubella, suggesting that greater disturbance of the skin in measles is less productive than greater hyperplasia of superficial lymph nodes in rubella.

There are also plasmoid pathological cells, but these are not true plasma cells (polyblasts), and, though they may enter the blood, never are Türk cells.—I am, etc.,

London, Oct. 14

ROBERT CRAIK, M.D.

Food Advice for the Waiting Out-patient

SIR.—The part which doctors and nurses play in aiding the national food policy is at present small because nutrition is a matter on which they are seldom consulted by their patients except in cases of illness, and then it is more often the special diet than the general aspect that arises. In spite of the efforts of the Ministry of Food that are everywhere apparent and applauded, enlightenment on the best food to buy within the restricted choice available and the most beneficial methods of cooking it are limited, because the Ministry lacks the means of reaching the housewife by personal contact. A great opportunity to overcome this difficulty exists in the out-patient departments of hospitals and in the maternity and child welfare clinics throughout the country, where hundreds of thousands of women congregate daily. The initiative to exploit this opportunity should come from those responsible for the hospitals and clinics.

At the Soho Hospital for Women we are attempting to give advice on food and cooking to a minute fraction of this large group of the population. We have been enabled and encouraged to make the experiment by the good offices of Dr. B. S. Platt of the staff of the Medical Research Council and by the co-operation of the London County Council, who have been so good as to give us the services of one of their expert advisers on domestic economy and cooking. This lady comes to the out-patient department once a week, and having made a typical housewife's daily food purchases on the way demonstrates their uses and abuses. This is not done in a formal lecture, which would prolong the out-patients' wait and discourage them, but in talks to a few patients at a time before or after they have been seen by me. The demonstrations are proving popular, and the patients and their friends have expressed their gratitude for the service. The secretary of the hospital will be very pleased to show the scheme in working to anyone who is interested and will communicate with him.—I am, etc.,

London, W.1, Oct. 25.

W. C. W. NIXON.

Medical Students and Help for Russia

SIR.—It was with feelings of grave disquiet that many old students of University College Hospital must have seen in the Press that the students of the hospital had communicated with the Prime Minister with the object of influencing the decision as to the type of assistance to be given to our great ally, Russia? This is comparable to the demands, often made by the relatives of a sick person, that "something must be done"—a demand which, in the interests of the patient, has to be resisted until the appropriate time for action arrives.

It is hard to believe that the spirit of Wilfred Trotter should so soon have ceased to influence the students of his own hospital. I suggest that they, and indeed all medical students, should—as part of their education—read and re-read his papers. These have recently been published in book form.—I am, etc.,

Nottingham, Oct. 13.

S. ALAN S. MALKIN.

Obituary

PROFESSOR O. FOERSTER

Otfrid Foerster, whose death at the age of 68 has recently been announced, was one of the foremost neurologists of the age. He had all the attributes of a great clinical teacher. He was a shrewd diagnostician with a singularly retentive memory for cases; he had a vast knowledge of the neurological literature of all countries; he wrote well and lectured brilliantly; and he lived for neurology. His voluminous writings range through the whole neurological field, but through them all he is seen as the perpetual student of the structure and function of the neuromuscular apparatus of man, and it is for his contributions in this field that he will be longest remembered.

Foerster was brought up in Breslau, where his father was a professor of classics. After graduation he spent two years abroad, mostly with Dejerine, but also with Frenkel-Heiden in Switzerland, from whom he acquired a lasting interest in the physical therapy of disorders of movement. When he returned to Breslau he was put in charge of the neuro-anatomical laboratory by Wernicke, and became director of the neurological clinic at the municipal hospital. About 1907 he introduced the operation of posterior root section for tabetic pains and spastic states. He began to operate, first in collaboration with his surgical colleagues Tietze and Küttner, and then alone. His subsequent achievements in the operation of chordotomy and in removing intramedullary tumours of the spinal cord stamp him as a careful and successful operator, but he always remained a rather ungainly craftsman. To one so fragile as he increasingly became the long neurological operations must have been a severe physical ordeal. But his fiery spirit drove him onwards towards his main objective, which was a systematic study of the effects of stimulation and excision of different parts of the nervous system. He had an immense capacity for work, habituating himself to three or four hours' sleep a night.

In the 1914-18 war he was consulting neurologist to the Sixth Army Corps at Breslau, where he collected peripheral nerve and spinal cord injuries. This work formed the basis of two important monographs, the one on some 4,000 personal cases of peripheral nerve injury, the other on 395 cases of war injury of the spinal cord. After the war there was an interlude when he was persuaded to spend a year in Russia looking after Lenin in his last illness.

In 1917 he had become full professor of neurology at Breslau, and in 1921 he had a department in the Wenzel-Hancke Krankenhaus, to which later was added, with the aid of the Rockefeller Foundation, an Institute of Neurology. He continued his peripheral nerve and spinal cord work, and also introduced and developed the surgical treatment of post-traumatic epilepsy. Between 1927 and 1937, amidst the manifold activities of a leading neurologist, he produced at least six monographs of first-class importance, including those on the pathways of pain, on the motor and sensory fields of the cortex, and on voluntary muscles and their disorders. In this last work, published in 1937 in the *Handbuch der Neurologie*, which he edited with Bumke, he revealed himself as probably the greatest living authority on the action of muscles. This was knowledge which he had gathered from stimulation of muscles and nerves during many operations on peripheral nerve lesions, and from systematic clinical analysis of the disorders of movement that followed paralysis of the different muscles. He was strongly influenced by the writings of Hughlings Jackson and Sherrington, and by the writings of Hughlings Jackson and Sherrington, and clinical neurology was for him the means of applying to man the doctrines and research of these two men whom he deeply revered.

Amidst many academic honours the greatest, he told a German colleague, was the Hughlings Jackson Medal of the Royal Society of Medicine, presented to him at the International Congress in London in 1935. For his Schorstein lecture at the London Hospital, as a tribute to the work of Henry Head he reported his observations on the dermatomes in man. He had

a passionate veneration for learning, and his last years were saddened by the disappearance of scholarship from Germany.

He had a wide circle of friends in many countries, and especially in the United States, where on one occasion he acted as surgeon-in-chief at the Peter Bent Brigham Hospital for his friend Harvey Cushing. His pupils include Ludwig Guttmann, Altenburger, Gagel, and Penfield; there would have been more of them if he had had laboratory facilities in earlier years, for he was a great stimulator of young men. There are many who will remember with pleasure and regret their visits to his clinic at Breslau, and the convivial evenings—his one relaxation—when Foerster enriched their lives from his great store of knowledge.

H. C.

Foerster's death will be regretted by his many English friends. He spoke English fluently, and in recent years delivered the Schorstein memorial lecture at the London Hospital and the Hughlings Jackson lecture. It is of interest just now to recall that he attended Lenin in his last illness, and had the highest opinion of the Bolshevik leader's intellectual and administrative ability. Foerster performed the necropsy and removed the brain. Lenin died of cerebral arteriosclerosis, which Foerster believed was in part the result of an injury to his internal carotid artery in an assassination attempt. At the end of his life Lenin was having fifteen to twenty Jacksonian attacks daily, but continued to work at his desk.

At first, as a physician, Foerster had to be content with Nature's experiments, but surgery offered him wider scope, for an operation could often be planned so as to ask a physiological question and evoke an answer. This was the basis of his contribution to knowledge of cortical function and of the sensory pathways.

Foerster's slight and stooping figure gave, at least during his later years, an impression of frailty; but his voice and vigour of speech expressed his toughness and tenacity. His mind was inductive, searching, and analytical, and he was untiring in the pursuit of truth, which led him in the end to lonely places.

W. R. R.

DAVID ORR, M.D.

The news of the death of Dr. David Orr came as a shock to his many friends. He had just returned from a holiday, and was apparently in perfect health, when, on the evening of October 8, he dropped dead at his home in Grange Road, Edinburgh.

David Orr was born in 1872 and educated at George Watson's College, Edinburgh. He qualified in 1894 after a distinguished career, taking the degrees of M.B., C.M. at Edinburgh University, and M.D. in 1902, with special commendation for his thesis. After qualifying he studied diseases of the eye at Moorfields Hospital, London, and for a time was clinical assistant in the ophthalmic wards at the Edinburgh Royal Infirmary. Postgraduate work followed at Heidelberg and Vienna, and on returning to Scotland he worked for some time with the late Sir Thomas Clouston at Morningside, then as assistant medical officer at Melrose Asylum, and later as assistant pathologist to the laboratory of the Scottish asylums. In 1898 he was appointed A.M.O. and pathologist to the Prestwich Asylum, Manchester, being promoted deputy superintendent in 1911 and medical superintendent in January, 1924. Unfortunately his health broke down in the following year, and he retired in November, 1925. Since then he had lived in Edinburgh, but resumed research work in the laboratory of the Royal College of Physicians in that city.

Orr was an indefatigable research worker, and during his time as pathologist to Prestwich Asylum he published in *Brain*, the *Journal of Mental Science*, and the *Review of Neurology and Psychiatry* numerous papers recording the results of his work in his own laboratory and in Prof. Lorrain Smith's department of pathology at Owens College, Manchester. Many of these papers were written in collaboration with the late Prof. R. G. Rows, and among others with Drs. T. P. Cowen and J. Stephenson. Much of this work dealt with the pathology of acute insanity, the influence of toxins on the central nervous system, and the paths of infection through the lymphatic system and the spinal cord. This work was of fundamental importance and remains as a valuable contribution to neuropathology.

was thoroughly conversant with the literature of his subject in German, French, and Italian, and paid several visits to the Continental clinics and laboratories. In 1909 he published with Dr. Rows a translation from the Italian of Lugaro's important work *Modern Problems in Psychiatry*.

None of those who were privileged to work with him will ever forget his vivid personality and that buoyant enthusiasm and optimism which he shed round him. He was one of those who bear about with them "the infection of a good courage," and so can "meet all life's ills and accidents with gallant and high-hearted happiness." His main interests outside his work were golf and music. He sang well and had a fund of good stories, and an evening in his hospitable home was something that lived in the memory of his host of friends. He is survived by his widow and two daughters, with whom deep sympathy is felt in their sudden bereavement.

W. S.

R. M. S. writes:

David Orr was not only an enthusiastic research worker, but was an excellent teacher who could not fail to exercise a great influence on his junior colleagues. His contributions to neuropathology were initiated in Ford Robertson's laboratory, where he introduced several improvements in methods of staining nerve tissue. In 1902 he presented for his M.D. a thesis on the pathology of acute insanity. This was largely concerned with the morphological changes in nerve cells and fibres and was published in *Brain*. But with the passage of years much less importance is now attached to chromatolytic changes in diseases of the nervous system, and Orr will chiefly be remembered for his experimental work on lymphogenous infection of the nervous system, much of which was undertaken in collaboration with the late R. G. Rows. In these studies proof was furnished of the passage to the posterior columns of the spinal cord of toxins from local lesions of peripheral nerves, and these observations on animals were followed by a study of the spinal cord in neurosyphilis and particularly in tabes dorsalis. As an outcome of this work, Orr and Rows were led to the conclusion that the early tabetic process was induced not, as Obersteiner and Redlich had claimed, by mechanical pressure of local meningeal overgrowths at the point where the posterior root nerve fibres penetrate the pia mater, but by the syphilitic toxin circulating in the lymph channels among the roots. Though to-day the teaching of Richter and Hechs largely holds the field, the possibility of the passage along perineural lymphatics of the treponema or of its toxins has never been seriously challenged. Orr's pupils will keep in grateful memory his buoyant enthusiasm, his wide erudition, and the outstanding and pioneer part he played in psychiatric research.

H. EDMUND G. BOYLE, F.R.C.S.

The passing on of H. E. G. Boyle, at the age of 66, at the end of a long and particularly distressing illness, must have come almost as a relief to his numerous friends, however much they will deplore the loss of his genial and stimulating personality.

Born and educated in Barbados, he came to St. Bartholomew's for his medical training, and although during his career he served a number of other institutions for varying periods, such work was always more or less incidental, and it was Bart's that was throughout the chief scene of his work, the centre of his affections. There he was early appointed one of the two resident anaesthetists, and when after a few years thus spent the authorities found it necessary to increase the anaesthetic personnel he, in company with his late colleague, W. Foster Cross, was promoted to the visiting staff, in which capacity he gave to the hospital loyal and continuous service until his quite recent retirement owing to ill-health. He had then been senior anaesthetist to the hospital for many years, and was at once elected on to the consulting staff.

It was during the period of his most active work that great advances began to be made in the science and practice of anaesthesia, which had for many years been in a somewhat static condition. In these changes Boyle certainly took a very

prominent part. Always more interested in the practical rather than the purely scientific side of his speciality, he was quick to see how each new advance could best be put to practical service, and the actual improvements that were made during this period in administrative technique were probably due more to him than to any other single individual. His work in this direction was largely stimulated by the visit he made to the United States and Canada to investigate and evaluate the newer methods that were coming to the front across the Atlantic. There he travelled widely and made close personal contacts with all the leading anaesthetists—men like Gwathmey, McKesson, McMechan, and Wesley Bourne, to mention only a few. He came back still further strengthened in his advocacy of the gas-oxygen and gas-oxygen-ether combinations which he had always recommended. The present writer well remembers helping him to unpack the first Gwathmey gas-and-oxygen apparatus that came to this country and his enthusiasm over every detail. He soon himself devised numerous alterations and improvements, and so resulted the Boyle's gas-oxygen (ether) apparatus, the name of which is a household word in operating theatres. Not content, however, in establishing the potentialities of gas-oxygen (ether) anaesthetics in general surgery, he set himself to elaborate suitable techniques for its use in special surgery, such as that of the ear, nose, and throat, thoracic operations, and midwifery. Another branch of anaesthesia in which he was, if not a protagonist, at any rate one of the earliest and most successful workers, was that of endotracheal anaesthesia.

In addition to holding staff appointments in various other general and special hospitals Boyle, during the last war, held a commission as Captain in the R.A.M.C.(T.), and for his services to the Army was awarded the O.B.E. in 1920. As a Fellow of the Royal Society of Medicine he was an active and by no means silent member of the Section of Anaesthetics, the presidency of which he held in 1923. He was a member of the Editorial Board of the *British Journal of Anaesthesia* from its foundation and also an original member of the Association of Anaesthetists of Great Britain and Ireland. When, largely at the instance of the latter body, the Conjoint Board established the Diploma of Anaesthesia he was one of the earliest to be granted that diploma, and was one of the first pair of examiners appointed to conduct the examinations. In 1935, under the special regulations, he was elected a Fellow of the Royal College of Surgeons without examination.

A very important part of his many years' service to St. Bartholomew's was that of lecturer and teacher of anaesthetics in the Medical College. He was a good and stimulating lecturer, but he himself attached far more importance to the practical instruction he gave to his clerks. His book, *Practical Anaesthetics*, was much appreciated by students, and the third edition, with which his colleague, C. Langton Hewer, was associated, is still current. But quite apart from anaesthetics, Boyle was intensely interested in any and all of the activities of his hospital. As a student he was president of the Abernethian Society, and he always followed closely the activities and fortunes of the various athletic clubs, especially those of the Rugby Union. As a senior member of the staff he was for a period president of the Students' Union. He married in 1910 Mildred Ethel, daughter of Mr. J. W. Widdy and widow of Mr. Leslie Greene, F.R.I.B.A., who survives him. Much more could be written about the numerous activities of "Cocky" Boyle, both at work and at play; but to the writer, who had the privilege of being particularly closely associated with him in the anaesthetic service of St. Bartholomew's Hospital for many years, the strongest memory that will remain is that of a truly genial and loyal colleague.

C. F. H.

Dr. CHARLES EDWARD THOMAS, of Conwys Eifed, South Wales, died on September 12, at the early age of 28, after a long and painful illness. He was a student of St. Mary's Hospital, London, and, graduating M.B., B.S.Lond. in 1937, held an appointment as medical officer at the Royal Devonshire Hospital, Buxton. He left Buxton in August, 1938, and returned to St. Mary's as a patient, afterwards being moved to Harefield, where he died. Dr. Thomas joined the British Medical Association immediately after qualification.

Medical Notes in Parliament

THE NATION'S HEALTH AND MEDICAL SERVICES

In the House of Commons, on October 21, Dr. HOWITT initiated a debate on the health of the civil population. He said that the health of the people had been extraordinarily good, and the fears entertained at the beginning of the war had not materialized. Still, we must hold on firmly to all the preparations which had been made to deal with the possibility of epidemics. At the beginning of the war a great mistake was made in evacuating so many cases of tuberculosis from the sanatoria back to their homes. Steps had already been taken to get these people back to sanatoria, but there was a danger in the contacts in the homes to which they had returned. All persons who had come into contact with such infectious cases should be carefully examined.

With regard to the health of the people after the war, it was of the utmost importance to plan and think now. The Minister of Health's statement on October 9 on the hospital policy of the Government after the war would become a historical landmark in the foundation of a great medical service in this country. The secret of success in the hospital service would be to get a proper partnership between all workers, municipal and voluntary, so that they could share and pool all that was best. They wanted to have a service in which it was possible for everybody to have quick attention, the patient going to the general practitioner and the general practitioner being able to obtain special help locally. They were going to have the finest health service this country and the world had ever known, but only if workers were willing to sink their differences and work together heartily to that end. He hoped that after the war there would be a great increase in the number of nursery schools.

Mr. MESSER said that the voluntary hospitals ought to be replanned, but rather more comprehensively than was outlined in the Minister of Health's speech. Why was it, he asked, that the municipal hospitals were left out of any office in the E.M.S., and that at the head of each sector a representative of the voluntary hospitals was appointed? Voluntary hospitals in the modern world were an anachronism. The doctors and staffs of the voluntary hospitals had done a great work in the past, but it was in the past. The time had come when what was done by indiscriminate charity should be done by the community for the community. Why did the Minister say that special arrangements would be made to finance the teaching hospitals? Not a word was said about the possibility of the municipal hospitals becoming teaching hospitals.

VOLUNTARY VERSUS STATE HOSPITALS

Sir FRANCES FREMANTLE said that to sweep away the voluntary hospitals and bring them entirely into a State service was not the way in which we had developed in this country, and was not the way in which sound development would take place. Old traditions were the roots from which the State services sprang and would develop. In the hospitals a wonderful service had been developed, with extraordinary inequalities and deficiencies, but with extraordinarily good results. There were undoubtedly many voluntary hospitals which had outworn their day and managements also. That was why co-operation between the State service and the voluntary service was so useful. He believed that, while the voluntary system was valuable, they must have some kind of interference by the State in the management of the voluntary hospitals. That, he took it, was one of the matters to be considered in the survey to be made by the Minister of Health.

He hoped that after the war, instead of the big hospitals rebuilding in London, they would keep only casualty and reception stations and one or two special departments that were necessary, and an administrative office, and would shift the patients out to the country. He would like to see the hospitals, whether voluntary or municipal, become collective centres of all the services required for health. The medical officer of health should have his offices there. Small clinics ought not to be scattered about; they should be in parts of the same

building. The hospital ought to be the centre of research, of private practice, and of preventive medicine.

Dr. EDITH SUMMERSKILL said they were told that the voluntary hospitals had always been supported by charity, and that there was something ennobling and fine in this. She saw nothing ennobling in the way voluntary hospitals were financed to-day. These hospitals, because they had insufficient funds, were economizing at the expense of their patients. Was there anything fine in asking sometimes as many as 100 seriously sick people to sit in an out-patient department waiting their turn for attention? Was there anything fine in asking men and women who were seriously ill to wait for five or six weeks, or even two months, before they could be admitted to voluntary hospitals? This outworn system must be replaced by a State-aided system.

An ideal health service must be so arranged that the workers in it were given not only adequate pay but limited hours, and, in this particular field, an opportunity for postgraduate study. She hoped that the time would come when no general practitioner without a higher surgical qualification was allowed to operate in some of our small cottage and voluntary hospitals. Many people had no opportunity of availing themselves of any insurance scheme for medical service. The people among whom there was an increase in tuberculosis were chiefly those who would wait perhaps weeks or months before seeking advice, because they were unable to avail themselves of the health services. The Minister should remember, in planning, that we should never reduce diseases unless everybody was given the opportunity of going to a doctor irrespective of income. She would like to see not only the voluntary hospitals taken over by the State but the profit motive eliminated from the treatment of disease, and all persons in the country have an opportunity of availing themselves of State medical services.

SUGGESTIONS FOR THE GOVERNMENT INQUIRY

Captain ELLISTON said that the Minister's promise of a comprehensive hospital system providing every form of medical and surgical treatment for every person in need of it in every part of the country represented an outstanding advance in the development of the health services. This question of hospitals was so urgent that it could no longer be postponed. There would have to be an inquiry as to the best size of hospital units. We wanted advice regarding the transfer of bombed hospitals from noisy, crowded areas to more suitable sites. There was also the question of increased provision of private wards for paying patients. The survey committee would have to consider the relative incidence of conditions requiring treatment in various population units. The survey must be conducted by persons with open minds and wide experience, and with no axes to grind for any vested interests or established systems.

No doubt those responsible for the survey would recognize all the good that there was in the voluntary system, but if the municipal hospitals were given a fair chance they could take their place side by side with the voluntary institutions, and medical men of distinction would be proud to be associated with them. They should be entitled to a fair share of clinical material, and should not be regarded as mere homes for chronics or incurables. When the waiting lists in the voluntary hospitals had been abolished, the municipal hospitals would be in a position to contribute a greater share to the teaching of medicine, and should be great places for refresher courses where general medical practitioners could keep in touch with the latest developments in medicine in a way they had never yet had an opportunity of doing.

CO-OPERATION INSTEAD OF POLITICS

Prof. A. V. HILL said he deprecated hostility between the voluntary and State hospitals or between the upholders of the two systems. He dissented from Dr. Summerskill's depreciation of the working of the voluntary system. Dr. Hill said changes were necessary and new measures required, but it was a pity not to recognize the great good that existed in the present arrangements and the great achievements of medicine and the public health services in the past. The inherent humanity of the hospital system must be preserved, and they must try to get the good they could from the existing systems and graft on to

it the good in other systems. It was essential, if good results were to be obtained, that individual parties in the compromise should not play politics, but should work together for the public good.

It was clear that there must be a universal medical service at some time, both for preventive work and for the treatment of individuals. Many of them were convinced that it should be based on the family, and the experiment which had been made at the Peckham Health Centre was one they would like to see developed. Many younger medical people were very socially minded, and he was very much inclined to let them develop in their own way. If they let things develop there was every chance of obtaining the kind of medical arrangement that many of them looked forward to. He could not believe that a State service was necessarily inefficient. He deprecated any attempt to lay down beforehand how far they should go in any direction. As an experimental scientist, he said that the important thing in medicine was to experiment. Let them take the systems, let them develop side by side, find out what was good, find out what was bad and discard it, and in that way progress by evolution. The Minister's proposal for strengthening the hospital system was a step in the direction of gradual development which they all welcomed, but they would have to go a good deal further.

Dr. HADEN GUEST drew attention to an article in the *British Medical Journal* for September 27 by Dr. Laidlaw and Dr. Macfarlane, analysing the incidence of pulmonary tuberculosis in Glasgow. Their conclusion was that the cause of the increase in the cases of tuberculosis was a combination of long hours, overtime, strain, and ill-spent leisure. That was not what one would have expected in the ordinary way to cause the increase in tuberculosis, which was a poverty disease and depended on malnutrition. He thought this was occurring all over the country where industrial conditions prevailed. We were not using our great public health organizations at present to avoid an increase in that kind of disease. Medical officers of health could be switched over in wartime to the supervision, control, and direction of all the conditions of life of the people employed in industry. The functions of medical officers in the Army were to keep the Army fighting fit. Those functions were carried out by supervising all the details of life, ranging from clothing, billets, and camping accommodation to hours of work and sleep and to morale. Supervision of the hygiene and welfare of factory workers had not yet been placed on a satisfactory footing. The total number of medical officers engaged in the supervision of men engaged on production was insufficient compared with the number in any of the Forces.

Referring to the medical organization after the war, Dr. Haden Guest said that at present the greatest epidemic of typhus fever ever known in European history was raging in Spain. There was typhus fever in Russia, and there were epidemics of malaria and other illnesses in other parts of the world. At the end of the war we should have the greatest world public health problem to face that we had ever known. It was more urgent than the precise relations between voluntary and municipal hospitals that we should have an organization capable of dealing with this problem.

Government Reply

Mr. ERNEST BROWN said that in a few weeks' time he hoped to have a shortened report which would incorporate such available statistics over the whole field as would give a fair and reasonable guide to the trend of public health, because it was vital that they should have an understanding, not merely of the things they had to do now, but of the things they would have to do in the future. The health of the nation, considering the extraordinary changes in population and the abnormal life people led in the periods of raids, had been surprisingly good. It was bad, psychologically, to be always talking of epidemics, except in so far as that discussion might lead to preventive action. They wanted to make as widespread as possible the services which made for the health of the nation and to spread more widely than ever a simple, elementary knowledge of the things to be done in the home and elsewhere which helped to keep people fighting fit. A great deal had been and was being done in that field, and he paid tribute to the admirable work done, in liaison with the Ministry of Health and other bodies,

by the Central Council for Health Education. A series of pamphlets which had been produced dealt with very difficult problems, and included one on scabies and impetigo. That had given him and every medical officer of health in every area concerned not only furiously to think but furiously to act. In reception areas they were having to provide scores of new sick bays so that that particular ailment might be dealt with properly and effectively. They would have, however, to go nearer to the root of the matter, and a little later on he hoped to make an Order, under a Regulation which had now come into force, which would give the medical officer of health more power in regard to inspection.

SOME VITAL STATISTICS

On the general position as regards health, the Minister said that the general death rate in 1940 was 14.3, including air-raid deaths of civilians. That figure was not comparable with those of recent years, because deaths of non-civilians had been excluded since the outbreak of war. The figure for 1939 was 12.1. The 1939 figures relating to diseases in England and Wales must be taken with a little caution, because in the great movements of population notification had probably been a little slower than previously. The infantile mortality rate was 56 per 1,000 births in 1940, 6 per 1,000 above the low record of 1939, but lower than the rate for any year before 1938. The maternal mortality rate per 1,000 declined to a new low record of 2.61, compared with 2.82 in 1939. No doubt a great deal of that had to do with the wartime maternity hostels set up in the reception areas. In the wartime maternity homes alone nearly 30,000 babies had been born in this period of the war.

The condition of public health generally remained satisfactory. In the early part of 1940 there was an appreciable increase in cerebrospinal fever and a recurrence to a less marked extent in the early part of this year. The incidence fell from 1,380 in February to 420 in September, and the mortality rate of this disease had been reduced in the last few years to one-third of the previous figure. Measles, which had been prevalent in the past eighteen months, had almost completely disappeared at present, the figure of new cases for September being 2,768, against 29,804 in September of last year and 62,737 cases at the peak in February of this year. Scarlet fever and diphtheria had never been high, and the incidence was less than in the corresponding months of last year, and approximately the same as in 1939.

TUBERCULOSIS : POSITION EXAMINED

With regard to tuberculosis, the experience in England and Wales had happily not been quite the same as in Glasgow. In 1913 the death rate from pulmonary tuberculosis per million was 958; in 1918, 1,165; while in 1939 it had been reduced to 476. The figures for the first quarter of this year would show that there had been a reduction of 7% over the whole field compared with the first quarter of 1940. He hoped to have these figures out within a fortnight, and those for the second quarter as soon after as might be. In 1913 the rate for young females between 15 and 25 was 1,020, and by 1918 that had gone up to 1,580. Owing to the increase of services and the attention given, it was down in 1939 to 762. Members had called attention to the 1940 figures compared with the 1930 figures, rising to 881 in that group per million. The first quarter of 1941 showed a slight decline of about 4% in that group. Those figures illustrated the progressive improvement in general social measures as well as in particular health services, and especially in housing, between the wars. He regarded housing as a vital health service and the foundation of the health services.

Directly he had seen these figures, he instituted an inquiry by his own people, with the Medical Research Council, and asked for an interim report on the causes of the rise. He hoped to get that interim report as quickly as might be. He could not agree too much with what had been said about hours of strain. All who followed the interesting series of reports on industrial fatigue in wartime, instituted in 1917, had long ago come to the conclusion that they could not, over any long period, equate production with hours. The ideal was to have such a state of strength and health and skill that they got the maximum production in the normal working day. With

regard to the tuberculosis services, it was necessary to make the preparations they did for the casualties that had not yet occurred. In doing so they had had to limit somewhat the number of beds. He had that matter under attention, and beds had been released, but they were up against the problem not only of beds but of nurses, and they were giving urgent attention to that. He was aware of the shortage of domestic staff which existed, not merely in regard to tuberculosis, but in all the hospitals. He was sure that the authorities responsible for carrying out in this vital field the duty imposed on them by Parliament would not merely continue but would intensify their efforts to deal with contacts.

With regard to his recent statement, it was true, as Mr. Messer had said, that in the E.M.S. the London Sector Officer was from a voluntary hospital. In fairness to those who devised this organization, it must be added that each officer had two deputies, one for the voluntary hospitals in the Sector and one for the municipal hospitals. In each Sector also there was a voluntary and a municipal lay sector officer, and a voluntary and a municipal matron. This duality was also in force at headquarters. At the Ministry of Health, under the Director of the E.M.S. concerned with the London Region, there was a deputy drawn from the municipal side and one from the voluntary side.

People who would like to abolish voluntary hospitals had expressed their views in the debate that day. On the other hand, there had been a gratifying indication that the House understood that they could have confidence in the democratic representatives who would come into the discussions and make these schemes after a survey. He had deliberately used the word "partnership" to describe the intended relationship between the voluntary and municipal hospitals. So far as he and his administration were concerned, they would take the guidance of Sir Francis Fremantle and other members who had spoken, and would not cease to look for opportunities in war to find an additional service which might continue when the war was won and they could carry on the great improvements that were in progress when it began.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on October 17 the following medical and surgical degrees were conferred:

M.B., B.Chir.—J. S. Johnstone, D. E. Marmion, D. S. Cadman, J. M. Stansfeld, Rees Jenkins, I. G. Wickes, R. C. Southern, O. L. Scarborough.

M.B.—J. R. Griffith, W. S. Nutt.

UNIVERSITY OF WALES

WELSH NATIONAL SCHOOL OF MEDICINE

The following candidates have satisfied the examiners at the examinations indicated:

M.B., B.Ch.—*Hygiene*: M. S. Berkovitz, T. W. Brokovski, J. E. Crane, J. D. P. David, Sadie M. Davies, Megan B. Evans, E. H. Horton, H. J. Houghton, M. E. Humphreys, Dorothy M. Hyde, R. T. James, A. E. Jones, E. R. Jones, J. H. Joseph, Gwyneth M. Lewis, *W. C. D. Lovett, Flora Macaulay, B. F. Martin, T. F. McCarthy, *D. McCracken, Tessie Phillips, Annie M. Rees, *R. D. Richards, Dorothy Roberts, D. Shiers, A. K. Toufcoq, D. G. Tutton, H. G. Williams, S. E. Williams.

D.P.H.—*Part II*: D. T. Thomas.

* With distinction.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Lectures

The Moynihan Lecture on "The Ileo-gastric Syndrome" will be delivered by Mr. L. R. Braithwaite before the Royal College of Surgeons of England at the Royal Society of Medicine (1, Wimpole Street, W.) on Tuesday, November 4, at 2.30 p.m.

Dr. W. E. Gye, F.R.S., will deliver two Imperial Cancer Research Fund lectures before the Royal College of Surgeons of England at the Royal Society of Medicine on Thursdays,

November 6 and 13, at 3.30 p.m. The subject of his first lecture is "Cancer of the Breast" and the second "Filterable Tumours."

On Wednesday, November 26, at 2.30 p.m., Dr. A. P. Cawadias will deliver the Thomas Vicary Lecture on "Hermaphroditism" before the Royal College of Surgeons of England at the Royal Society of Medicine.

The lectures are open to medical practitioners and advanced students, as well as to Fellows and Members of the College.

Prophit Research Studentship

A candidate will shortly be nominated by the Council of the Royal College of Surgeons of England for a Prophit Studentship in Cancer Research. The studentship will not exceed the annual value of £500, with an allowance not exceeding £200 for expenses of travelling, and will be for one year in the first instance, but renewable at the discretion of the special trustees on the nomination of the Council of the College. Students may be male or female. Applications, giving a statement of the proposed research and accompanied by a recommendation from a member of the staff of the applicant's medical school or university, should be sent to the Secretary, Royal College of Surgeons of England, Lincoln's Inn Fields, W.C.2, before November 22.

The Services

ARMY AWARD

The M.C. has been awarded to Lieut. Kenneth Cameron Powys Thomson, E.A.A.M.C. (attached King's African Rifles), in recognition of gallant and distinguished services in the Middle East.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL ARMY MEDICAL CORPS

The death was announced in October in the Middle East of Major ROLAND NEVILLE-JONES. He was educated at the University of Birmingham, where he graduated M.B., Ch.B. in 1934. He took the M.R.C.S., L.R.C.P. in the same year and the D.A. of the English Colleges in 1936. After holding hospital posts at Birmingham, including those of junior medical officer at St. Chad's Hospital, senior resident anaesthetist and house-physician at Queen's Hospital, and house-surgeon at the General Hospital, he settled in practice at Purley, Surrey, in 1936. He entered the R.A.M.C. as lieutenant early last year. He leaves a widow.

Prisoners of War

Temporary Major John Malcolm Fosbrooke.
Lieut. Richard Maurice Solomon.

Missing at Sea

Captain Ernest John Frank Hinde.

ROYAL AIR FORCE

Acting Squadron Leader JAMES RUSSELL MCWHIRTER, who was killed in a motor accident on August 31 while serving in the Canal Zone, was born on December 5, 1909. He received his medical education at Queen's University, Belfast, graduating M.B., B.Ch., B.A.O. in 1934. After holding house appointments at the Royal Infirmary, Bristol, St. Luke's Hospital, Chelsea, and the Archway Hospital, Highgate, he was granted a short-service commission in the R.A.F. on May 3, 1937, was promoted to flight lieutenant in 1938, and recently to acting squadron leader. For two years he served at various flying training schools and qualified as a pilot in 1939. Early in 1940 he was posted to the Middle East Command and shortly afterwards was transferred to the Reserve on completion of initial service on the Active List and remained employed as a Reserve Officer.

DEATHS IN THE SERVICES

Lieut.-Colonel HUGH ALLAN DAVIDSON, D.S.O., R.A.M.C. (ret.), died in a nursing home at Aberdeen on October 12, aged 63. He was born at Kennethmont, Aberdeenshire, on May 28, 1878, and was educated at the University of Aberdeen, where he graduated M.B., Ch.B. in 1900. He took the D.P.H. three years later. Entering the R.A.M.C. as lieutenant in November, 1900, he became lieutenant-colonel in 1918, and retired in 1920. He served throughout the war of 1914-18, was twice mentioned in dispatches, and received the D.S.O. and clasp, and the Croix de Guerre.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 11.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year for: (a) England and Wales (London included), (b) Ireland, (c) Scotland, (d) Northern Ireland, (e) The Channel Islands.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1941					1940 (Corresponding Week)

* Except for Northern Ireland, typhoid and paratyphoid are now notified separately.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes enteric and paratyphoid for Northern Ireland.

§ Owing to evacuation schemes and other movements of population birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales a decline in the number of notifications of whooping-cough and paratyphoid fever was recorded for the sixth consecutive week. The number of cases of scarlet fever, measles, and diphtheria increased—119, 72, and 37 in excess of the totals of the preceding week. The rise in the notifications of scarlet fever has not been shared by the South-Western counties, where the trend has been fairly constant, whilst for the other main divisions and for the whole country the incidence has been doubled during the past three months. The increase in the notifications of diphtheria has become fairly general throughout the country, with the exception of the South Midland and Eastern counties, where the incidence has fluctuated around a constant level. A large rise in the number of cases of diphtheria occurred in Scotland, 73 more than in the preceding week: the increased incidence was distributed throughout the western area. The notifications of scarlet fever, whooping-cough, and measles showed small increases in Scotland.

Poliomyelitis

With an increase of 7 cases in England and Wales, the number of cases of poliomyelitis reverts to the level of a fortnight ago. The notifications were distributed over a wide area, and no county returned more than 3 cases. Multiple cases occurred in Lancashire (Manchester C.B. 3), Leicestershire (Shepherd U.D. 2), Middlesex (Ealing M.B. 2), Norfolk (Norwich C.B. 2), Surrey (Caterham and Warmingham U.D. 2). No cases were reported in Berkshire, Buckinghamshire, or Oxfordshire, where the recent outbreaks have been the most important numerically. Nine cases were reported from Scotland, compared with 6 in the previous week, the multiple cases being in Glasgow (5) and West Lothian county (2).

Dysentery

In England and Wales 207 cases were notified, compared with 108 in the preceding week. This is the biggest weekly total since the spring of 1938. The largest of the local outbreaks was in Kent, where 63 of the 64 cases were reported from Tonbridge U.D. Increases were recorded in Gloucestershire, Somersetshire, and Lancashire, where 29, 18, and 22 cases were notified, compared with 17, 2, and 10 in the preceding week. The increases in the first two counties were due to Bristol C.B. (24) and Weston-super-Mare M.B. (15). In Lancashire the cases were distributed through eight administrative areas, the largest number of cases in these districts being that of Manchester C.B. (9). In Scotland notifications fell from 175 to 100 as a result of the subsiding of the outbreak in Lanark county, where 27 cases were notified, compared with 103 in the preceding week. Glasgow (21 cases), Dundee (14 cases), and Edinburgh (10 cases) were the centres of the other local outbreaks.

Quarterly Returns for England and Wales

The return for the first quarter of 1941 has just been published by the Registrar-General. The birth rate of 14.4 per 1,000 and the infant mortality of 75 per 1,000 live births were both below the average for the first quarters of recent years. The death rate was 17.5 per 1,000, as compared with 19.9 in the first quarter of 1940, but was above the average of 14.6 per 1,000 for the five years before 1940.

Week Ending October 18

The number of cases of infectious diseases notified during the week in England and Wales included scarlet fever, 1,195; whooping-cough, 1,979; diphtheria, 1,002; measles, 783; cerebrospinal fever, 107; poliomyelitis, 50; dysentery, 143; paratyphoid, 62; and typhoid, 16.

The national scale of salaries for chartered masseuses and masseurs holding appointments in hospitals, institutions, clinics, etc., has recently been revised by the Council of the Chartered Society of Massage and Medical Gymnastics. The new scale has been approved by the Ministry of Health for members working in E.M.S. hospitals. Copies may be had from the wartime address of the Society: Mount Lodge, Amersham, Bucks.

Medical News

A conference on historical aspects of the medical services will be held by the Socialist Medical Association at 12, Great Newport Street, W.C.2, on Sunday, November 2, beginning at 11 a.m. Papers will be read by Mr. H. L. Beales, Dr. T. O. Garland, and Mr. Arnold Sorsby.

Lieut.-Colonel Macbeth Wilson will deliver a lecture on "Physical Symptoms due to Emotional Causes" at the Weston Hotel, Bath, on Thursday, November 6, at 5.30 p.m. All Service medical officers and civilian practitioners will be welcomed.

A meeting of the Tuberculosis Association will be held at 26, Portland Place, W., on Saturday, November 8, with the following programme: 9.45 a.m., council meeting; 10.25 a.m., general meeting; 10.30 a.m., short papers by Dr. Alexander Capes, Dr. R. Cruickshank, Dr. R. H. Dobbs, Dr. J. Smart, Dr. E. T. W. Starkie, and Mr. O. S. Tubbs; 1.15 p.m., lunch at Welbeck Palace Hotel; 2.30 p.m., informal meeting to discuss problem cases and to show interesting x-ray pictures.

The recently published August issue of the *Irish Journal of Medical Science* is devoted to the reports of the Dublin Maternity Hospitals.

Dr. J. W. Trevan, director of the Wellcome Physiological Research Laboratories, has been elected a director of the Wellcome Foundation, Ltd.

Dr. Francis G. Blake Sterling, professor of medicine, has been appointed dean of the Yale University School of Medicine.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Attilology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Congested Hands and Brittle Nails

Dr. CYRIL G. EASTWOOD, medical officer of health for Weston-super-Mare, writes: Dr. Frank Matthews and "Stasis" (October 18, p. 568) have both propounded problems in your "Queries and Answers" column for which an identical remedy should prove useful. The congestive condition of the hands and brittleness of the finger-nails (due to constriction of the nail-bed capillaries) are both features found in chronic arthritis. The injection of histamine will give immediate relief to both patients, and the method of use will be found in a paper of mine in the *Journal of State Medicine*, 1935, p. 720.

Dr. G. B. EDLESTON (tuberculosis officer, Kent County Council) writes: In reply to Dr. Frank Matthews's request (October 18, p. 568) for advice in the case of his patient suffering from thin, brittle nails of fingers and toes and from chilblains, conditions of long duration, I suggest that the patient may be afflicted with Boeck's sarcoidosis, with which disease the names of Besnier and Schumann are also associated. Dr. Matthews does not say if his patient suffers from chilblains all the year round; but if she does that fact may be a strong point in the diagnosis of pseudo-tuberculosis. Lupus pernio is not restricted to the cold seasons, ulcerations never develop, and the nails frequently show dystrophic and atrophic changes. It would, therefore, be well worth while for Dr. Matthews to have his patient's chest, hands, and feet x-rayed to exclude manifestations of Boeck's sarcoids in the lungs and all three types of sarcoidotic lesions in the metacarpal and metatarsal bones.

Income Tax

Board and Lodging of a Locumtenent

C. B. D.: (1) A practitioner has shut his own house and boarded out the locumtenent, paying the landlady a weekly sum arranged by himself. Is this amount assessable on the locumtenent? (2) The practitioner makes an allowance of £50 per annum to the locumtenent, who uses his own car. Can that be held to cover petrol and oil, as well as tax, insurance, wear and tear, and running repairs?

*(1) No. The fact that the board and lodging are not provided directly by the employer is immaterial so long as he, and not the locumtenent, is liable to the landlady for the weekly payments. (2) There is no legal bar. If the locumtenent expends (including the wear-and-tear allowance as if it were expenditure) more than £50 per annum wholly, exclusively, and necessarily in the performance of his professional duties, he can claim an allowance for the excess.

LETTERS, NOTES, ETC.

Liq. Ferri Perchlor. Fortis for Impetigo and Sycosis Barbae

Lieut.-Colonel J. H. SMITH, I.M.S. (ret.), writes: I have read a number of letters recently in the *Journal* on the treatment of impetigo, and wish to suggest what I have found to be a very simple and effective treatment, which cures the condition in a matter of days. Paint liquor ferri perchlor. fortis (it must be fortis) on the affected parts and on an area of healthy skin surrounding them. There is no need to remove the crusts; it is quite sufficient to apply the solution liberally over them; they will fall off in two or three days, leaving healthy skin underneath. After three daily applications I usually give the patient an ounce or so of the ferri perchlor. and tell him to look carefully in the glass every morning for a week or two for any new or oozing spots, and to dab them as soon as they appear. This treatment is equally efficacious for sycosis barbae. I believe that one thorough application cures this condition. The patient should, in the same way as above, watch for a few days for new spots appearing. If those who are dissatisfied with the present treatments will try the above I feel sure they will find it a great advance on the methods recently recommended. I have used it since seeing it recommended in the *British Medical Journal* some years ago for diverse skin troubles, many of which had resisted other methods of treatment, and have got excellent results from its application in almost any form of staphylococcal infection. I am at present treating a number of troops suffering from these conditions, and some of the patients who had been under treatment for weeks (especially with ointments, which appear to spread the condition rather than cure it), were discharged in three or four days after a daily application, and given liq. ferri perchlor. fortis 5j to take away and apply as stated above.

Humphrey Clinker and White Bread

Mr. THOMAS GUTHRIE, F.R.C.S. (Pembury, Kent), writes: In view of present-day efforts to encourage the use of wholemeal as opposed to white bread, the following passage from *The Expedition of Humphrey Clinker* is of interest. Matt. Bramble, on a visit to London, has many reasons for preferring life in the country; one of them is shown by the following quotation: "The bread to eat in London is a deleterious paste, mixed up with chalk, alum, and bone-ashes; insipid to the taste, and destructive to the constitution. The good people are not ignorant of this adulteration: but they prefer it to wholesome bread, because it is whiter than the meat of corn: thus they sacrifice their taste and their health, and the lives of their tender infants, to a most absurd gratification of a mis-judging eye: and the miller, or the baker, is obliged to poison them and their families, in order to live by his profession." *Humphrey Clinker* was published early in 1771, a few months before Smollett's death.

Medical Aid for China

Dr. MARY L. GILCHRIST, honorary secretary of the China Medical Aid Committee, writes: In the month of July you very kindly published on our behalf a letter signed by Lord Horder. I think your readers will be interested to hear that nearly £400 was raised by the press appeal.

Request for Microscopes

The Education Department of the Royal College of Nursing (Henrietta Place, Cavendish Square, W.1) is needing additional microscopes for laboratory work in connexion with the sister tutor course. Owing to the present difficulty in securing these, the Director in the Education Department would be grateful to hear from anyone who might be able to lend or allow the College to hire one or more of these for the session. It has been suggested that there might be some of these instruments unused at the present time owing to their owners' absence from London.

PREPARATION AND USE OF CONCENTRATED RED CELL SUSPENSIONS IN TREATMENT OF ANAEMIA

BY

G. E. O. WILLIAMS, M.D.

Deputy Regional Blood Transfusion Officer, E.M.S.

AND

T. B. DAVIE, M.D., F.R.C.P.

Regional Blood Transfusion Officer, E.M.S.; Professor of Pathology, University of Liverpool

The establishment of blood banks has greatly increased the use of blood transfusions, not only in the most urgent cases of hæmorrhage and shock and for the more severe and resistant cases of chronic anaemia but also as a means of shortening the convalescence of patients suffering from anaemias of less severity, many of whom would probably recover ultimately without resort to such treatment. From the point of view of the individual patient as well as from that of national economy it may often be justifiable to utilize the blood of one healthy person to enable another to return to work at an earlier date than would otherwise be possible; but the growing tendency to substitute intravenous transfusion of blood for the oral administration of iron results in a constant drain on the supply of blood now urgently required for preparation of plasma. The transfusion habit now being established may also cause serious embarrassment to the blood transfusion services in peacetime, for such a useful therapeutic weapon will not willingly be surrendered at the conclusion of hostilities.

Large-scale preparation of plasma from stored blood, however, has made available considerable quantities of red cells in concentrated form. These red cells, amounting to about 50% of the original volume of whole blood, are usually discarded, which in view of their potential value in the treatment of anaemia is particularly regrettable.

Suspensions of red cells separated from the plasma have been used in the past for the treatment of anaemia, but with few exceptions these suspensions were diluted with saline to such an extent as to make them more dilute than normal blood (Robertson, 1918). The use of the red cells in concentrated suspensions has recently been described by MacQuaide and Mollison (1940). At the time their article was published a few cases of anaemia had been treated by the Liverpool Regional Blood Transfusion Service with similar concentrated suspensions, and since then these have been used in increasing amounts.

Preparation of the Suspensions

At the regional laboratory of our transfusion service plasma is withdrawn from all bottles of blood, irrespective of group, on the seventh day of storage, up to which time they have been available for transfusion as "whole blood" wherever required. The stocks of blood stored in each individual hospital, which under present conditions are considerably in excess of the normal transfusion requirements

of civilian medical practice, are similarly processed. The technique of plasma separation is the "closed" method described by Edwards and Davie (1940). In this process the plasma is aspirated through a long needle inserted through the perforated metal cap and rubber diaphragm which closes the bottle. After separation of the plasma (a process which can be performed aseptically) the aspirating needle is plunged to the bottom of the red cell layer and aspiration of the concentrated red cells is continued into a fresh sterile bottle. The layer of gelatinous material which normally lies on the surface of the red cells and consists of leucocytes, platelets, and fibrin is carefully left behind in the blood bottle. The last remaining drops of cells in the needle and tubing are transferred to a tube of citrate-saline solution for grouping and cross-matching. The red cells of another bottle of blood of the same group, and, if necessary, of a third bottle, are added to those of the first, a specimen of these cells being similarly retained for grouping, etc. A bottle of concentrated red cells will therefore consist of contributions from two or three donors. The citrated sample tubes of cells are attached by a rubber band to the neck of the bottle of concentrated cells. Cross-matching of each sample with the serum of the patient is occasionally undertaken by the clinician, but is generally performed in the laboratory before the bottle is issued for use. These concentrated suspensions are usually prepared only at the request of clinicians, but it is sometimes convenient to anticipate the demand by preparing a small stock of bottles of assorted groups. These are stored in the refrigerator for forty-eight hours, after which time those not used are discarded.

Nature and Composition of Concentrated Red Cells

Specimens of concentrated red cell suspensions prepared by the present method show considerable variations in their haemoglobin and cell content. This is mainly due to individual differences in the rate and extent of cell sedimentation in citrated blood under conditions of storage.

The following figures are quoted as being fairly typical of the results obtained from examination of a sample of concentrated red cells:

Haemoglobin (Haldane)	..	150%
Red cells	..	8,500,000 per c.mm.
White cells	..	3,000 per c.mm.
Corpuscular volume (Wintrobe)	..	85% (normal for whole blood, 45%)

The most important difference between stored blood and fresh blood is the increased corpuscular fragility of the former. This is mainly due to the fact that the anti-coagulant solution of 2.5% sodium citrate is hypertonic and produces in the blood corpuscles a state of increased intracellular osmotic tension. When such red cells are placed in contact with isotonic saline solutions they exhibit greatly increased fragility, since by comparison with their contents their new surroundings are now hypotonic (Maizels and Whittaker, 1939). Another possibility is that venous blood, by reason of its high CO₂ content, is somewhat more fragile than either capillary or arterial blood (Whitby and Hynes, 1935).

It was suggested by MacQuaide and Mollison that a small amount of hypertonic (1.1%) sodium chloride solution should be added to the suspensions in order to reduce their viscosity and thus facilitate their administration. Before adopting this procedure ourselves a few preliminary experiments were performed to determine the resistance of blood cells to 1.1% saline solution after they had been stored for seven days. Red cell counts of specimens of stored blood were made, using as a diluting fluid normal human serum of the same blood group. Duplicate counts were also performed on the same specimens, using 1.1% saline solution as the diluent. Any reduction of the red cell count in the saline compared with that in serum would indicate the degree of haemolysis that had occurred in the former solution. The counting pipettes, containing the red cells diluted 1 in 200 with the respective diluents, were left at room temperature for fifteen minutes before being finally shaken and counted. In one such experiment the discrepancy between the results of the two counts amounted to as much as 1.7 millions per c.mm., or approximately 20% of the total. This represented a degree of *in vitro* haemolysis that would be incompatible with safety in a bottle of blood intended for transfusion. It was therefore decided that the addition of 1.1% saline to suspensions of concentrated red cells as prepared by us would be inadvisable. In any case, this dilution has not been found necessary, as no insuperable transfusion difficulties have been experienced on account of increased viscosity of the concentrated suspensions.

The apparent increase in the fragility of stored red cells does not appear to have the clinical significance that one might be led to expect. There seems to be no direct relation between the fragility of the red cells, as measured by the usual test of resistance to hypotonic solutions of sodium chloride of varying concentrations, and the rate of their destruction in the body of the recipient. This contention is supported by recent investigations into the survival time of stored blood cells after transfusion experiments which have shown only slightly longer survival of fresh cells as compared with those stored for a week, in spite of the greatly increased fragility of the latter (Mollison and Young, 1940).

Administration

Although the increased viscosity of suspensions of concentrated red cells slows the flow through the delivery apparatus, no modification of the standard blood transfusion outfit as supplied by E.M.S. transfusion centres is necessary beyond lengthening the transfusion rubber tubing to provide a greater head of pressure. When giving concentrated red cell suspensions in any quantity it is important that the flow be regulated to approximately 100 c.cm. an hour to avoid the risk of cardiac embarrassment by rapid addition of a viscous fluid to the circulating blood, particularly as the myocardium of an anaemic person may have undergone pathological changes which impair its efficiency.

The indications for the administration of concentrated red cell suspensions are such that it should seldom be necessary or even advisable for them to be given as an urgent or emergency measure, since supplies of plasma and Group IV (O) whole blood are available to every hospital for emergency transfusions. Concentrated suspensions should therefore be used only for cases of chronic anaemia which require rapid replacement of haemoglobin and red cells with minimal increase of circulating blood volume.

Results of Treatment

Material for over 150 transfusions of concentrated red cells has been issued in the past eight months. Of these transfusions over sixty have been administered to two patients suffering from aplastic anaemia, but owing to certain special features these cases have been omitted from the present series. Information regarding responses to transfusions, in terms of elevation of haemoglobin percentages and of changes in the red cell counts, has been procurable in only 38 transfusions, administered to 35 patients. These results for convenience of comparison have been tabulated, together with other data relevant to the cases, in Table I. Fair comparison of these results is

TABLE I.—Summary of Results of Transfusions

Case No.	Amount given (c.cm.)	Hb% Before	Rise in Hb %	R.B.C.s before Transfusion (in millions per c.mm.)	Rise in R.B.C.s (millions per c.mm.)	Rise in Hb % per 500 c.cm. conc. R.B.C.s	Condition

Unfortunately rendered difficult by the fact that blood counts and haemoglobin estimations, although in most cases performed by experienced pathologists, include variations taken by several different standards and under varying circumstances. These individual findings are therefore more than usually liable to error, and are of somewhat limited value as data upon which scientifically accurate conclusions may be based. They are presented here simply as evidence from which our own clinical impressions were formed.

Owing to the wide variety of conditions which have been treated with concentrated red cells these results have been classified into four main groups, as follows:

- Group I: Post-haemorrhagic anaemias (7 cases).
- Group II: Anaemias associated with severe infection (6 cases).
- Group III: Anaemias of pregnancy and the puerperium (4 cases).
- Group IV: Dyshaemopoietic anaemias (pernicious, aplastic, and idiopathic hypochromic anaemias) (7 cases, 8 transfusions).

To compare the individual responses, the percentage rise in haemoglobin for each case was calculated for a "standard transfusion" of 500 c.cm. (approximately one bottle) of concentrated red cell suspension. The mean response to a standard transfusion was obtained for each group of cases, and graphs were prepared by plotting these individual results in terms of percentage rise of haemoglobin per 500 c.cm. of suspension. These, with the mean in each group, are illustrated in Figs. 1 to 4.

Graphs showing Calculated Percentage Rise of Haemoglobin per 500 c.cm. of Concentrated Red Cell Suspension. (The mean of each series is represented by a horizontal broken line at the appropriate level. Figures along base line refer to case numbers.)

FIG. 1.—Group I: Post-haemorrhagic anaemias.

FIG. 2.—Group II: Anaemias associated with severe infection.

FIG. 3.—Group III: Anaemias of pregnancy and puerperium.

FIG. 4.—Group IV: Dyshaemopoietic anaemias.

In the first, or post-haemorrhagic, group the results show wide range of scatter about the mean. Allowance for 5% error in haemoglobin estimation, however, places all except one of the readings within reasonable limits of variation. The four readings which fall outside these limits include two cases with very low responses (Nos. 6 and 17), both of which were suffering from chronic gastric complaints, the one being a carcinoma and the other a recurrent peptic ulcer that proved fatal two weeks after transfusion. The other two cases (Nos. 15 and 56) showed abnormally high responses to transfusion. These were both cases of chronic uric haemorrhage of non-malignant origin which were transfused immediately before operation, and the second haemoglobin readings of which were performed soon after operation. Omission of these four cases from the series

would reduce the mean of this group from 14.3% to 12.8% haemoglobin per 500 c.cm. of concentrated blood.

The second group of post-infective anaemias, although too small to provide conclusive evidence, shows a surprisingly high average response to transfusion. From the subsequent histories of these few patients it appears that cases of septicaemia associated with anaemia are very much improved by transfusion therapy. We now therefore recommend, for severe cases of this kind, repeated transfusions of concentrated red cell suspensions until the haemoglobin is over 60%. When this level has been attained fresh whole blood, which is richer in antibodies and contains active leucocytes, is of greater benefit, and transfusion with this should be continued until the haemoglobin is at least 90%. This treatment should, however, be additional to rational anti-infective measures.

The results of four cases of anaemia associated with pregnancy and the puerperium are shown in Fig. 3. Little may be deduced from our findings in these cases, but clinicians have been impressed with the value of concentrated red cell transfusions in rapidly rehabilitating patients who might otherwise remain in a state of chronic debility and vague ill-health as a result of nutritional or post-haemorrhagic anaemia.

The graph illustrating the dyshaemopoietic group (Fig. 4) shows a considerable variation in the responses of the individual cases. Two cases showing very poor results (Nos. 14 and 18) were respectively severe pernicious anaemia with subacute combined degeneration of the cord (which ultimately made a good recovery) and a case of aplastic anaemia. The latter patient failed to respond to transfusion treatment, and died a few weeks later. There is reason to believe that in both these cases the haemoglobin estimations were faulty. Their omission from the series would have raised the mean increase of haemoglobin per 500 c.cm. transfusion from 8% to 10% for this group.

From these results we are able to conclude that, irrespective of the nature of the condition causing the anaemia, transfusion with one bottle of 500 c.cm. of concentrated red cell suspension raises the haemoglobin between 10% and 12%. Exceptions to this occur, and are usually low responses due to a rapid exacerbation in the factors causing the anaemia. Unexpectedly high results have in some cases been attributable to operations which have not only removed the cause of the anaemia but may also have produced some degree of haemoconcentration.

Reactions

Reports of the incidence of reactions following the use of concentrated red cell suspensions were obtained regarding 77 transfusions which were given to 61 patients. In all, fifteen reactions of all grades were noted, the gross reaction rate thus being 19.5%. Reference to Table II shows that this series consisted of five Grade I reactions (slight elevation of temperature), two Grade II reactions (pyrexia with slight shivers but no definite rigor), and seven Grade III reactions (definite rigors associated with rise of temperature).

This apparently high rate of rigor production (amounting to 9.1% of all transfusions) may be attributable to the peculiar circumstances in which the Liverpool Regional Transfusion Service was placed during three months of the period under review. Enemy action had destroyed the apparatus necessary for the production of distilled water, and the supply of 2.5% sodium citrate solution had therefore to be obtained from other sources, under circumstances that made it impossible to guarantee the exclusion of pyrogens. To this was attributed the fact that during this period the reaction rate (all three grades) among patients receiving stored whole blood had risen to an exceptionally

high figure—more than double the incidence before this period. Of the 77 transfusions of concentrated red cells 21 were given during this three-month period, and accounted for four out of the seven Grade III reactions and three others of less severity. The exclusion of all transfusions administered during this period gives a Grade III reaction (rigor) incidence of 3 in 56 transfusions, or 5.35%.

TABLE II.—Details of Cases showing Reactions to Transfusion

Case No.	Sex	Age	Group	No. of Transfusions	Hb % Before	Amount of C.B. given (c.cm.)	Hb % After	Details of Reaction	Diagnosis and Results
Grade I Reactions (T. 100° or over, Without Symptoms)									
16	F	—	2	1	58	1,000	—	Temp. 101° following day	Post-natal anaemia
29	M	63	2	2	24	2,000	89	Temp. 100.2° after first transfusion	Pernicious anaemia
48	M	65	2	2	45	850	78	Temp. 100° after second transfusion	Haematemesis
50	M	28	4	1	—	500	56	Temp. 101°	Haematemesis. Ordinary blood given, with no reaction
52	F	32	4	1	30	900	55	Temp. 100°	Ulcerative colitis
Grade II Reactions (T. over 100°, with Slight Shivering)									
63	M	39	4	2	50	400	—	Slight rigor after first transfusion	Haematemesis
47	F	46	4	2	28	900	42	Slight rigor after first transfusion	Aplastic anaemia
Grade III Reactions (Definite Rigors, with Pyrexia)									
1	M	—	4	2	50	500	—	Rigor; temp. 101° after first 100 c.cm.	Papilloma vesicae. Remainder of transfusion given next day
15	F	43	4	1	35	500	70	Rigor; temp. 101° following day	Cervical polyp
22	M	—	4	1	35	700	45	Rigor (reaction)	Sepsis and amputation
33	F	30	3	2	28	350	28	Rigor with first transfusion	Post-natal anaemia. No reaction with second transfusion
43	F	37	3	2	35	500	—	Rigor with first transfusion	Severe septicaemia. Rigor? not due to transfusion. Given old suspension on second occasion and became jaundiced
55	F	54	4	1	50	1,000	—	Rigor; temp. 102°	Carcinoma ventriculi; pyrexial before transfusion
60	M	37	2	1	—	400	—	Rigor; temp. 103°	Haematemesis. Improved
Grade IV Reactions (Anaphylactic Phenomena, etc.)									
31	F	26	—	1	34	500	—	Urticarial oedema	Complete abortion. Oedema subsided with adrenaline

Our gross reaction rate thus appears to have been considerably higher than it might have been in the absence of any disturbance of our laboratory routine. Corrected for this, the impression is confirmed that, as stated by MacQuaide and Mollison, the incidence of reactions to transfusions of concentrated red cell suspensions is no higher, and probably is lower, than that produced by the use of stored whole blood.

In addition to the febrile reactions discussed above there remains a group of reactions which appear to be due to some hypersensitivity on the part of the recipient to some component of the transfused fluid. They are not peculiar to concentrated red cells, for they occur also after plasma transfusions. These reactions would seem to be of an allergic nature, as is illustrated by the case reported in Table II under the heading "Grade IV Reactions." In this case no harm was done, as the oedema that resulted subsided after the administration of adrenaline. One fatal reaction, which appeared to have been due to a similar mechanism, occurred following one transfusion of con-

centrated blood, and owing to its importance the case is here reported in full.

A woman aged 46 (Case 35) was admitted to hospital with a history of menorrhagia, and complaining of dyspnoea and palpitations; there were also signs of anaemia. Blood examination shortly after admission showed hypochromic anaemia, the haemoglobin being 35% and the red cell count 2.3 millions per c.mm. The menorrhagia was found to be due to a cervical polyp, and as a preliminary to operation the patient was given a transfusion of concentrated red cells, starting at 6.45 p.m. on April 2, 1941. Three hours later she was rather restless, but felt drowsy. Six hours after the transfusion was begun she was pale and cyanosed, with deep stertorous respirations. The heart rate was 160 per minute and the radial pulse not palpable. The transfusion, almost completed, was then stopped, and the patient given morphine, grain 1/6, oxygen; and coramine. She died in coma at 1.45 a.m., seven hours after the start of the transfusion. Post-mortem examination revealed a large, pale, flabby, and grossly dilated heart, with numerous ecchymoses, averaging about 5 mm. in diameter, scattered upon the surface of the interventricular septum. Some of these petechiae appeared to involve the left branch of the bundle of His. There was no lesion of the heart valves or of the coronary arteries, and no evidence of thrombosis of the saphenous vein. The spleen was enlarged to about double its normal size. Incompatibility of blood was excluded by direct cross-agglutination tests performed before transfusion and repeated afterwards, while the slow rate at which the transfusion was given excludes the possibility of primary myocardial failure such as may have resulted from sudden loading of the right heart with transfused blood. The presence of petechial haemorrhages in the myocardium renders it probable that death was due to sudden disturbance of the conducting mechanism of the ventricles. While these changes may have been due to severe anaemia alone, in view of the circumstances under which death occurred it is possible that they were due to an anaphylactoid reaction following the transfusion.

This case emphasizes the importance of avoiding the use of blood likely to produce reactions of an allergic nature, but unfortunately we are not yet in a position to detect the sensitive patient in advance. The only precautions at present available against such accidents consist in scrupulously excluding from the panel of donors all those with a history of allergic manifestations and, where practicable, performing intradermal skin tests upon prospective recipients with a similar history, using a few minims of the transfusion fluid as an antigen.

Summary

The preparation and properties of concentrated red cell suspensions are described, and the advantages of their use in preference to whole blood in certain cases are discussed.

Results of 77 transfusions are reported, special reference being made to the percentage rise of haemoglobin per 500 c.cm. of suspension, and to the effect, if any, of the patient's clinical condition upon this result.

The frequency of reactions to this form of transfusion is calculated, and found to be considerably lower than that occurring when stored whole blood is used. One fatal reaction is described, and its aetiology briefly discussed.

We are indebted to numerous physicians and surgeons on the staffs of Merseyside hospitals, and to the medical superintendents of municipal hospitals in Liverpool, Birkenhead, and Wirral, for their permission to consult their case records, and to those resident medical officers and house-surgeons who have themselves contributed much valuable information about their patients. We are also grateful to Drs. Joy Cronin-Lowe, Sheila Kenny, and J. C. Millar for having provided us with their own personal observations of several cases. Finally, we are glad to record our appreciation of the work of Mr. J. Stainton and other members of the laboratory and secretarial staff of the Regional Blood Transfusion Centre, without whose assistance the present work could not have been completed.

MYCOSIS FUNGOIDES TREATED BY MALARIA, TERMINATING IN HODGKIN'S DISEASE

BY

HENRY MacCORMAC, C.B.E., M.D., F.R.C.P.

Physician for Diseases of the Skin, Middlesex Hospital

On May 29, 1931, a dairyman aged 45 presented himself at the skin department of the Middlesex Hospital with a seven-months-old eruption which had begun on the face and eyebrows and later extended to the pubic area, hands, wrists, and legs. The eruption was dry and scaly, except for some areas where moisture and weeping had occurred, thus conforming in its distribution and type to a seborrhoeic dermatitis, the diagnosis recorded at the first visit. As his progress covers a series of admissions to and discharges from the skin and medical wards the sequence of events can best be recorded under four different headings.

First Admission: May 30, 1931, to February 25, 1932

The initial phase of this remarkable history was represented by an eczematous eruption, in places dry, in other regions moist and weeping. The rash was considerable in extent, involving the face, arms, hands, trunk, and legs, and because of the dry scaly appearance in some places and the pronounced flexural distribution was labelled "seborrhoeic eczema." There were during this period fluctuations in the degree and extent of the eruption, with at times marked improvement, followed by an unexpected and disappointing relapse. The degree of itching was considerable and disproportionate, which might have hinted at things to come; and in places, for example over the arm flexures, the margins of the eruption presented an unusual raised or scalloped appearance, contrasting with the more characteristic eczema elsewhere. Although they have no special significance, it may be recorded that in September, 1931, abscesses developed in the calves of both legs, requiring surgical treatment. The Wassermann reaction was negative, and a blood count made on October 6 showed slight anaemia—9,800 leucocytes per c.mm., with the following differential count: polymorphs 61.5%, lymphocytes 23.5%, large mononuclears 0.5%, eosinophil cells 13.5%, and mast cells 1%. As in February, 1932, only some insignificant traces of the eczematous eruption remained, the patient was discharged from the ward to attend the out-patient department. In June, 1932, it was noted that on the trunk there were patches suggestive of the pre-mycotic phase of mycosis fungoides, but this diagnosis was not confirmed and definitely established until March, 1933.

Second Admission: February 23, 1934, to December 5, 1934

Mycosis fungoides was now present in an extensive form, including large sheets of pre-mycotic infiltration of the skin, with tumour formation in many areas. X-ray treatment had been in use from March, 1933, and had hitherto controlled the disease. But now, and for the first time, the eruptive process became so active and involved areas so considerable that x-ray treatment could no longer be employed with safety because the amount required to control the disease must have proved injurious or even fatal to the patient. A point had been reached when seemingly nothing further could be done. In 1933 I had published the beneficial effect of an attack of erysipelas on two cases of mycosis fungoides (MacCormac, 1933). Here seemed a therapeutic hint: the problem, then, was to produce a genuine infection which was accompanied by high fever, of a kind which could be brought under control at will. Malaria therapy seemed to satisfy all these conditions, and I therefore decided to ask the patient to consent to this treatment, explaining to him that it had never been in use for this purpose before, but that I had reason to believe it might succeed. As he had by now come to realize the formidable nature of his complaint and the limitations of our resources, he agreed to the experiment. Nevertheless, it was not without some hesitation that I arranged for an inoculation with malarial blood on April 4, 1934. This inoculation was successful, the reaction reaching a peak of 105° F. on April 15 and 16, and

finally being checked after some eight days by quinine treatment. The effect on the eruption was remarkable. As the fever reached its maximum both the tumours and the pre-mycotic areas melted away, leaving a skin almost normal in appearance. Seemingly the experiment had been a success. It soon, however, became evident that the improvement was not to be completely maintained, for in a lesser but nevertheless definite degree the tumours and pre-mycotic areas gradually returned. Here, nevertheless, was at least enough to warrant a second inoculation, which took effect on July 12, the artificially produced malaria being permitted to follow a course of some twelve days, accompanied by high fever and rigors. A repetition of the previous course of events was noted—i.e., a clearing up of the eruption and then some recrudescence. Nevertheless, by these two treatments the degree and extent of the disease had been so much reduced that it was now possible to resume x-ray therapy, and by it to arrest and check the now relatively small amount of eruption. It is interesting to record that in November, 1934, an intravenous injection of pyrifur was made, producing a temperature of 101.4° F. The result was disastrous: considerable new erythematous patches developed, and the original mycotic lesions were all aggravated, some days elapsing before the skin readjusted itself to its previous state. This experiment suggests, if no more, that it was not the fever as such but the underlying disease process, of which the fever was a symptom or reaction, that brought about the improvement; which may remind us of the distinction between artificial protein shock and the very complex reactions of a natural morbid process such as erysipelas or malaria.

Third Admission: April 8, 1936, to August 5, 1936

The period following the second discharge from the skin wards in December, 1934, up to November, 1935, can be described as one of comparatively good health. Then a deterioration set in. Severe backache was experienced, with vomiting and progressive anaemia. The spleen was considerably enlarged and there were palpable glands in the right axilla. All these symptoms could seemingly be accounted for by earlier conditions—the splenic enlargement being attributed to what was supposed to be the recurrent malaria, the enlarged glands to a neighbouring patch of affected skin, and the anaemia to the prolonged radiotherapy. On admission to a medical ward on April 8, 1936, the patient was pale and looked very ill. He complained of epigastric discomfort, occasional vomiting—not related to food—backache, and loss of weight. Of the previous extensive eruption there now remained only a dry patch over the right scapula and two small patches on the legs. The liver, spleen, and a group of glands in the right axilla were all enlarged. For some fifteen weeks there was present an irregular pyrexia up to 100° F., with occasional rigors. Blood counts made on several occasions showed an anaemia which persisted in spite of haematinics such as iron and liver. There was no evidence of haemolysis and no reticulocytosis. No malarial parasites were observed. The white cell count disclosed a leucopenia with a normal differential count. The absence of an eosinophilia calls for comment. On discharge from hospital on August 5, 1936, the patient is reported to have said that he felt quite fit, and his weight, which had fallen to 8 st. 7 lb., had then reached 10 st. 4 lb.

Fourth Admission

The fourth and last phase includes a period between readmission on September 22 and the death of the patient on November 19, 1936. The recurrence of the abdominal pain with rigors and pyrexia, the enlarged glands, liver, and spleen, together with other signs and symptoms, if not unquestionable, were at least favourable to the diagnosis of Hodgkin's disease, and this was supported by the microscopical examination of a lymphatic gland removed on October 7, 1936, which showed loss of structure, diffuse fibrosis, endothelial proliferation, and occasional giant cells of the Hodgkin type. Although there were no eosinophils Dr. Scarff reported that the appearances were strongly suggestive of Hodgkin's disease. Throughout the fourth admission the general condition steadily worsened. Ascites developed, there was pronounced anaemia with a leucopenia, the white blood cells dropped to 2,800 per c.mm., and a fall of blood pressure and progressive weakness terminated in death on November 19, 1936.

Necropsy (Bland-Sutton Institute, 231/36)

The following is abstracted from the post-mortem report:

"The right pleural cavity contained one pint of clear straw-coloured fluid: there were dense pleural adhesions over the surface of the left lung. The heart weighed 8 oz., and was wasted, although the muscle was firm. There was an ulcer measuring 1 inch by 1/2 inch in the oesophagus at the level of the bifurcation of the trachea. Deposits of a firm white growth were present in the upper lobe of the left lung, in the spleen, and in the liver. Those in the lung and spleen measured up to 1 1/2 inches in diameter, whereas those in the liver were larger, some having a diameter of 2 inches, umbilication occurring in the superficial tumours which projected above the surface of the liver: the spleen and liver were both enlarged, the former weighing 27 oz., the latter 116 oz. There were three pints of clear fluid in the peritoneal cavity. A section of the femur showed the upper three-quarters of the shaft filled with red marrow. Histological examination of the white masses showed proliferation of cells with large clear nuclei resembling reticulo-endothelial cells. There were also numerous giant cells exhibiting two or three darkly stained nuclei. Although only a few eosinophils were present, the appearances were those of acute Hodgkin's disease rather than a reticulum-celled lymphosarcoma."

Commentary

The illness and death of this patient, as recorded above, have served to throw some light, if in no more than a relative and small way, on the pathology and therapeutics of an obscure skin disease. Expressed in their simplest terms the facts are these. The patient developed first the characteristic lesions of mycosis fungoides: he was brought before the Dermatological Section of the Royal Society of Medicine on May 17, 1934, and again on December 19, 1935, the diagnosis being accepted by all those present on both occasions (MacCormac, 1934, 1936). As the result of malaria therapy the extensive eruption was finally reduced to three small patches, as noted on the third admission (April 8, 1936), being subsequently and up to the patient's death in November, 1936, negligible or absent. This introduced a new therapeutic principle. Further, the terminal transformation in this case of what was at first mycosis fungoides into what became Hodgkin's disease seems to establish the unity of these two clinical entities, a relation that has often been suggested. If the evidence in this case is considered good enough to establish this relation, then it follows that there is an aetiology and pathology common to both these forms of reticulo-endotheliosis. Nevertheless, as Sir Humphry Rolleston (1924) has pointed out, in the usual run of cases of Hodgkin's disease the changes are confined to the lymphoid structures—namely, the lymphatic glands, spleen, walls of portal vessels—and in the interstitial tissue of the lungs, kidneys, bone marrow, subcutaneous tissue, and serous membranes. Lymphadenomatous nodules in the skin are of extremely rare occurrence. Sir H. Rolleston had been able to collect only twelve cases in 1924: such nodules, I would venture to suggest, are in the nature of metastases. Since mycosis fungoides similarly keeps to its own territory, only rarely invading the deeper tissues or viscera, it would seem that the hypothetical virus has a sort of selective affinity for different parts of the reticulo-endothelial systems. Nevertheless the cure of the skin disease in this case did not prevent the subsequent development of a progressive and fatal form of reticulo-endotheliosis elsewhere. In another field—namely, that of micro-anatomy—there is to be obtained further support for the identity of mycosis fungoides and Hodgkin's disease, and in this connexion Civatte's (1936) authoritative observations in the *Nouvelle Pratique Dermatologique* may be quoted as follows:

"In lymphogranulomatosis and mycosis the infiltrates show a greater variety (as compared with the infiltrates of leukaemia).

Polynuclear neutrophils and eosinophils—and the latter sometimes in great abundance—lymphocytes, plasmocytes, and all the other polyblasts, are met with there in proportions which vary according to the case. But there are always a considerable number of large histiocytes with a voluminous nucleus and poor in chromatin, with a homogeneous and faintly basophil cytoplasm: sometimes these cells undertake the office of macrophages; they are thus genuine histiocytes. Here and there one of these cells is provided with a budding nucleus, and recalls a Sternberg cell; it is a transitional form. Sometimes even a true Sternberg cell is met with, identical with those which are seen in abundance in the glands in Hodgkin's disease. The diagnosis of cutaneous lymphogranulomatosis will be made if the clinical type is not clearly that of mycosis. But it must be realized that the most characteristic mycosis will also sometimes show genuine Sternberg cells. The microscope cannot, thus, distinguish between the two affections. Moreover, it is not certain that these are two different diseases: mycosis is perhaps only a special clinical type of lymphogranulomatosis, a pure cutaneous lymphogranulomatosis. It is known, moreover, that in certain cases an 'adenitis' appears in the terminal stages of the evolution of mycosis: the primarily cutaneous lymphogranulomatosis has invaded the glands."

Many authorities are prepared to go much further, creating a single and comprehensive group, the lymphoblastomas, embracing conditions both simple and malignant, such as lymphoid leukaemia, Hodgkin's disease, lymphosarcoma, and mycosis fungoides—the type-cell common to all being, according to M. H. Gordon, A. E. Gow, and Sir H. Rolleston (1937), the lymphoblast. The creation of this group relies upon intermediate and transitional forms which are deemed sufficient to link the whole together. The case recorded above serves only to relate two members of the larger group—namely, Hodgkin's disease and mycosis fungoides. From another source I am able to produce some evidence showing that mycosis fungoides is not malignant or cancerous or sarcomatous. In 1919 the late Dr. Henry Beckett, working in the Cancer Research Laboratories in the Middlesex Hospital, demonstrated that when tissue is fixed in weak formol Müller solution, stained with aniline acid fuchsin, and differentiated with picric acid alcohol, the Altmann granules which then appear are profuse in the cells of inflammatory exudates and of simple tumours, whereas they are absent or negligible in the cells of malignant growths. This differentiation is usually so well marked as to be apparent even when the slide upon which the section is mounted is held up against the light and examined with the naked eye, the redness or absence of redness due to the presence or absence of the acid-fast granules being then discernible in many cases. In 1913 the late Dr. J. J. Pringle brought a patient with mycosis fungoides before the Dermatological Section of the Royal Society of Medicine. In this case I had found giant cells (Sternberg cells) and had provided Dr. Beckett with tissue, which he prepared as described above and in which the Altmann granules were demonstrable in the cellular infiltrate in abundance. This, so far as it goes, favours the non-malignant nature of mycosis fungoides and, by inference, of Hodgkin's disease also.

In putting together the above record I have drawn upon the reports and clinical notes of my colleagues in the medical department and the Bland-Sutton Institute of Pathology, who have generously permitted me to make use of them. I am under an especial debt to Dr. Arthur Willcox, who when medical registrar had collected much of the material upon which this paper is based, and with whom, had circumstances permitted, I had hoped to collaborate.

THE T.N.T. HEALTH HAZARD

BY

HARRY M. ROBERTS, L.R.C.P.&Sed.,
L.R.F.P.S.Glasg.

Medical Officer, Nobel's Explosives Company, Ltd.

When toluol, or toluene, is completely nitrated with a mixed acid containing sulphuric and nitric acids, trinitrotoluene (T.N.T.) is produced. This is a pale yellow solid with a melting-point at about 80° C. Nitration is completed at about 100° C., the T.N.T. then separating out from the acid as a dark yellow oily liquid. The molten T.N.T. is washed with hot water until free of acid and is further washed with a solution of sulphite of soda to remove impurities. The purified T.N.T. is dried at 100° to 110° C. by running it through a steam-jacketed pan. The finished product can be obtained:

1. As flake, by cooling a film of molten T.N.T. on a revolving drum. A knife of brass which presses against the front of the drum removes the film as small flakes.

2. As crystalline powder, by cooling the molten T.N.T. in a pan, with slow continuous stirring. Lumps are removed by sieving.

3. As slab or biscuit, by allowing the molten T.N.T. to solidify in shallow pans.

4. As crushed flake, by passing flake between rollers and sieving to remove the larger particles.

Flake and crushed flake can be pressed into slabs. Crystalline powder and crushed flake are used in explosive mixtures—e.g., baratol, amatol, ammonal, and military ammonal with charcoal. Thus T.N.T. workers may be exposed to: (1) inhalation of fume from the molten variety; (2) inhalation of T.N.T. dust into the nose, mouth, and throat, with subsequent ingestion; and (3) skin absorption from contact with any of the above forms. Two of the above may coexist, for the vapour from molten T.N.T. will deposit as a crystalline dust on any surface colder than 70° C. Thus a worker thought to have fume contact only may, in addition, be exposed to ingestion. The effect of entry of T.N.T. into the system, the signs denoting entry, and the symptoms which may exist without signs, together with all measures necessary to prevent absorption, should be known to those responsible for the health of workers. The carrying out of such measures, including selection of those employed, should, under management, be controlled by a medical man or woman. Neither the State-registered nurse nor the experienced supervisor is sufficient to maintain adequate check on the hazard, although each is of great help if co-operating. Medical practitioners who lack industrial experience or who are unfamiliar with T.N.T. medical literature can be completely surprised, as is shown by the fact that recently several cases of T.N.T. toxic jaundice have not been recognized as such until within a day or two of death. Informative references recommended are:

1. "The Origin, Symptoms, Pathology, Treatment and Prophylaxis of Toxic Jaundice observed in Munition Workers": a discussion by certain Sections of the Royal Society of Medicine (January, 1917).

2. "Researches into the Toxic Properties of Trinitrotoluene," by Benjamin Moore, D.Sc., F.R.S. (On behalf of the Medical Research Committee; 1916).

3. "Trinitrotoluene Poisoning." Officially communicated by the Ministry of Munitions. (*Lancet*, 1916, 2, 1026.)

Prof. Moore's report is an account of an investigation into the properties and chemical reactions of T.N.T. during which conclusive experiments to determine the modes of entrance of the compound into the body were made. He describes the characteristic facies met with in many T.N.T. workers, and concludes with a description of Webster's test for the presence of T.N.T. in the urine. This report,

although published in 1917, can be accepted as being up to date.

The *Lancet* article embodies the Moore report, and is presented under the following headings: (1) digestive troubles, (2) blood changes, (3) channels of absorption, (4) differential diagnosis, (5) post-mortem appearances, (6) predisposition, (7) preventive measures and treatment. In an addendum Webster's test is described, with advice as to how the result should be interpreted. This article, in referring to cases of T.N.T. toxic jaundice in munition workers, states that 67% were caused by amatol and only 6% by ammonal, notwithstanding that ammonal contained the larger proportion of T.N.T. It suggests that the greater amount of ammonium nitrate in amatol was responsible, on account of its hygroscopic nature, for facilitating the passage of T.N.T. through the skin. Whatever justification existed in 1916 for regarding the compounds mentioned as standard in respect of their T.N.T. content, it would not apply to-day; for both amatol and ammonal vary considerably in the proportion of T.N.T. present. That wetness of hands caused by ammonium nitrate aids the entry of T.N.T. through the skin is debatable. T.N.T. is quite insoluble in ammonium nitrate, and absorption from solution would not arise. Some skins of fine texture may suffer breakdown of the epithelium from ammonium nitrate, which acts not unlike brine, and so the way be paved for absorption; but it should be kept in mind that the percentage of T.N.T. present is the factor which is the hazard and that the greater the contact with T.N.T. the greater is the health risk.

Schedule for Control of the Hazard

1. Selection of workers.
2. Record of physical condition on entry.
3. Record of sick absences.
4. Periodic examination for signs of T.N.T. absorption.
5. Record of T.N.T. stains in grades—for example, slight, gross, extensive—and also sites, such as hands, feet, under-clothing (shirts and stockings), overalls.
6. Co-operation with the works chemist in carrying out Webster's test; this to be done always by the same person if possible.
7. An arrangement that foremen, chargemen, supervisors, or other responsible persons draw attention to workers looking off colour and to any complaining of fatigue or breathlessness.
8. Insistence on provision of protective clothing and control of dust by adequate ventilation; also insistence on washing the hands before all meals, and both hands and face before going home.
9. A reserve of alternative work for those that have to be "stood off."

Selection of Workers

Selection is justified, for a definite health hazard exists, and under present conditions there should be no difficulty in placing rejected candidates elsewhere. Further, those susceptible to T.N.T. may not be protected by even the most satisfactory working conditions and meticulous supervision, and it is well to know the type from which they may spring. Cardinal points for guidance are age, average good medical history, fair but not necessarily high standard of physical fitness, and evidence of attention or inattention to personal hygiene. These factors possess a varying standard, according to whether the process is the manufacture of T.N.T. or the subsequent handling of the product as in shell and grenade filling. Not infrequently fewer health casualties are met with during the manufacture in bulk of a toxic substance than occur in workers using it as a component of other manufacture or in assembly. On manufacturing plant only men are employed in this country; their numbers are out of all proportion to the thousands of young women newly engaged in shell, bomb,

or grenade filling, and it is concerning these that recommendations as to selection apply.

Age is important, and 19 years should be the minimum for T.N.T. contact. Below this the incidence of susceptibility is high. In the war of 1914-18 persons aged 14, 15, and 16 years died from T.N.T. toxic jaundice after five or six weeks' work. Age in the upward direction is not significant, for middle-aged and elderly workers have been employed for many years in T.N.T. processes without suffering in health. In making selection avoid persons who show sweaty palms, for the orifices of the sweat glands will be open during work, thereby promoting skin absorption. Persons who sleep in underclothing worn at work add by this habit to the health risk. Anyone with a history of jaundice should be rejected. A yellow tinge in the sclerotic, often seen in those suffering from constipation, should call for rejection, because the colour alone will cause confusion at the periodic medical examination, while should constipation exist it will probably be habitual, which is a further objection. Long tapering finger-nails should be discouraged by supervisors, particularly when the finger-tip is not suited for this fashion, as explosive may lodge under the nail and be subsequently ingested. Nail-biting is for the same reason very objectionable, and evidence of this habit should be looked for, as it is resorted to whenever the hands are idle.

For women of 19 years body weight in indoor clothes of 120 lb. and upwards should be aimed at, and no female under 105 lb. should be exposed to T.N.T. contact. Such light-weight young women may be quite fit for effort, but, whatever the reason, experience has shown that it is in this class that T.N.T. sickness is apt to occur.

Recording Physical Condition.—Among other items age, height, weight, and history of anaemia or jaundice should not be missed. The weight will be of value later when dealing with cases under observation. Recent experience of many thousands of examinations is that in some areas a high percentage of women in the 20-30 year age group are 14 lb. underweight. A further point is that doctors are not furnished with physical details concerning persons allocated to them under the National Health Insurance Act, and when consulted by a new patient would not know if loss of weight had taken place.

Sick Absences.—For five months following entry into employment these should be recorded as a T.N.T. group and kept in a suspense file. At the termination of this probationary period all workers still fit can be regarded as normal in respect of exposure to T.N.T., but during the period absences certified as anaemia, gastritis, general debility, etc., should be the subject of investigation by the works medical officer, for often such certificates refer to a condition of malaise not definitely diagnosed. A Webster test at this stage is very useful, whether the result is negative or otherwise.

Periodic Inspection for Signs of T.N.T. Absorption

In the case of workers with less than four months' service inspection should be done weekly. After this period the frequency can be reduced, provided co-operation has been established between the medical officer and responsible persons on the job and with the welfare supervisor and factory nurse. A further essential to less frequent examination is that the medical officer should regularly scrutinize the entries recording attendance of workers at the ambulance room on account of indisposition or for such minor injuries as might facilitate the passage of T.N.T. through the skin. At the inspection the worker's hands should be examined and the T.N.T. facies looked for. On the hands brown tarry-looking stains may be found on

the palms and the palmar aspect of the fingers. These emit an odour which can be detected if sought for, and impart a bitter taste to the tongue. Staining may be found on the soles of the feet if T.N.T. dust is spilt on the floors. Undue staining should be recorded, for the stain is a reservoir from which T.N.T. may continue to enter the system after the worker has been "taken off." Gross staining may point to carelessness, to failure to use protective clothing, and, if on the scalp, to absence of head-covering. There is evidence that T.N.T. may be slightly soluble in fats and oils, for a greaser on a T.N.T. plant will incur large intense stains more readily than other workers. The significance of staining depends on its extent. Most workers will show it in some degree, and in the absence of symptoms or of a marked facies (referred to later) no particular notice need be taken.

The T.N.T. Facies

This is characteristic, and consists of pallor comparable to that of shock, with coloration at the lips, lobes of the ears, and curl of the helix. This appearance has been referred to as cyanosis, and the lips have been described as "ashen grey." These terms, more or less correct, fail to convey an exact picture, for the hue is brighter than cyanosis—it is lilac in shade. On the lower lip it is so unreal as to convey the impression that a mistake has been made in the lipstick used. The sites mentioned are selective: the coloration is never seen on fingers or toes. After some experience the T.N.T. facies is easily recognized. Two important points should be mentioned: it is greatly modified by excitement or recent exercise on the part of the worker—for example, hurrying to be in time for the inspection—and surprisingly so by artificial light. Under illumination through mellow-tinted globes it disappears, but becomes obvious when the worker steps into the daylight.

The T.N.T. facies has been ascribed to oxygen starvation resulting from conversion to methaemoglobin (or nitric oxide-haemoglobin) of the oxyhaemoglobin of the red cell by T.N.T., and to a vasomotor phenomenon unrelated to any blood changes. Regarding the former, it is known that the facies may be present while the person concerned remains symptomless as regards lack of oxygen. He or she may carry on normally, unaware of alteration in well-being and showing no sign of fatigue or breathlessness. Further, the facies will exist when the red cell count and haemoglobin percentage are normal for the particular person. Oxygen has been liberally administered by me, without appreciable change, to persons showing the T.N.T. facies. It is a fact that when a worker with this facies is removed to another job he loses the colouring—a change credited to reoxygenation, but which may not be the correct explanation.

Vasomotor Theory

In connexion with the tinting of the ear lobes it is interesting to recall that it was in the rabbit's ear that Claude Bernard first demonstrated the action of the vasoconstrictor fibres, and it is now known that capillaries as well as arteries are influenced by vasoconstrictor stimulation. Stimulation of the vasoconstrictor centre in the brain would, by bringing about stasis in localized areas, induce there an increased venosity of the blood. This explains why the facies can be obvious while the person concerned remains symptomless.

As illustrative of the application of the vasomotor theory to the T.N.T. facies, I refer to an appeal in the *British Medical Journal* of November 15, 1930 (p. 848) from the medical officer of a public school for diagnosis in the case of a boy who, after receiving dental treatment which left a fibre stopping in his incisor tooth, drew, while in the school laboratory, a few drops of aniline dye into his mouth from a pipette. He very soon

collapsed and developed on the face, neck, and hands a "deep blue-black colour." The replies diagnosed the occurrence as a case of aniline poisoning with formation of methaemoglobinemia. Commenting on the case, I drew attention (*Journal*, 1930, 2, 980) to the fact that there was not enough benzene chemical (nitro or amido) in a few drops of dye to cause methaemoglobinemia, and suggested that the dye soaked into the fibre stopping and dissolved in the lipoids in the incisive nerve and thus reached the brain. The blueness and the distribution could not have been a blood change, but could arise from action of the sympathetic or central nervous system, or of both.

The works medical officer would do well to keep both theories in mind. In the symptomless cases the vasomotor view explains the shock-like pallor of the cheeks, the tinted ear lobes, and coloured lips, but some types of T.N.T. poisoning may develop blood changes, and a symptomless case may through continued exposure become one of a different and serious type.

T.N.T. Absorption v. T.N.T. Poisoning

Not every case showing the T.N.T. facies, even when associated with a positive Webster test, should be regarded as T.N.T. poisoning or be notified as such, otherwise many unnecessary notifications will be made and the position as regards the T.N.T. health hazard confused. The dividing line between absorption and poisoning will, of course, be drawn according to the experience of the medical officer and the opportunities he has for clinical investigation—for example, Webster test, etc. The correct practice in cases in which the facies is pronounced and Webster's test is positive is to suspend such workers from T.N.T. contact (not from work) for a week or ten days. If the same worker requires suspension several times he is tested for susceptibility (see Webster's test), and the intensity of a positive result in relation to the amount of exposure he has been subjected to after a previous negative result determines whether or not he is classified "susceptible" and removed permanently from contact with T.N.T.

Symptoms which may accompany the characteristic facies and still retain the case in the category of absorption are: onset of breathlessness, constriction felt beneath the mid-sternum, and malaise. Symptoms which point to systemic poisoning are: gastric ache felt in the early morning; anorexia which has been preceded by increased appetite; physical and mental lassitude; jaundice, exceedingly slight at onset, often first observed as a tinge in the sclerotic; nausea and headache combined; and substernal constriction plus T.N.T. facies.

In some factories I have come across instances in which this substernal constriction was diagnosed as cardiac in origin and the worker certified to be suffering from heart strain. It is easy to make this mistake if the worker's doctor is unaware that the physical effort involved is most unlikely to cause heart strain, and also if the examination has taken place under bad or artificial lighting conditions. The symptom is more often met with in young women of the slightly anaemic type than in others, and the pain or ache complained of may be oesophageal in origin. When it is accompanied by a definitely positive Webster test the case is akin to that of gastric ache placed in the systemic poisoning category.

Doctors in munitions areas must not conclude from the scheme of medical supervision laid down as being essential that contact with T.N.T. necessarily creates sickness, for such is far from being the case. In a large munitions works in the North the manufacture of T.N.T. has gone on unceasingly for the past sixteen years without a single case of serious illness from T.N.T. contact, and many of the workers have been on the job all this time.

Webster's Test.—A description of Webster's test and its interpretation cannot (for reasons of space) be given here, but briefly it is a transient colour reaction indicating, when positive, that absorbed T.N.T. has been acted on during metabolism and has been excreted in altered form. The test in no way denotes systemic poisoning. Positive results can be graded from "trace" to "intense," and this standard helps greatly in the check-up on potential sickness and on susceptibles, since the intensity of a positive result can be considered in relation to the known exposure to T.N.T.

It cannot be too strongly urged on practitioners in munitions areas that they should make quick contact with the works medical officer when they are consulted by women who are exposed to T.N.T. and whose symptoms suggest an industrial origin. This attitude is particularly desirable when the altered health occurs within four months of employment.

THE PROBLEM OF OPERATION FOR RETROVERTED UTERUS

BY

CORALIE RENDLE-SHORT, M.B., Ch.B., M.R.C.O.G.

Tutor in Obstetrics, University of Bristol

Whether or not to advise operation in cases of backward displacement of the uterus has always been one of the most controversial subjects in gynaecology. The fact that there are so many different methods of correcting the retroverted uterus—some textbooks devote as many as eighty pages to describing different techniques—shows that there is no universally satisfactory method of operative treatment. However, although many writers either recommend or decry the operation, recent statistics of cases well followed up are not numerous. The out-patient departments of most gynaecological hospitals can produce several unfortunate women who have had some operation or other performed for backward displacement and are no better, and, perhaps what is even more important, the general practitioner who has persuaded some patient to have such an operation done, and finds her symptoms still continue, is puzzled as to what to advise for similar sufferers. In fact, he may get a general impression that all such operations are useless. The question remains, Is he justified in this opinion? It is a well-known fact that the grumbler always reappears: the cured and grateful patient often is not seen again.

The successful results of various operations for backward displacement can be divided into two classes: first, those which are an anatomical success, the uterus being in the anteverted position on examination; and, secondly, those which are also cured of their symptoms—subjective success. It has been found that these two do not always go together.

The Literature

As usual, American writers report the largest number of cases. Graves and Smith (1931), examining 3,358 patients, found that after two years the anatomical cures were 75%, symptomatic cures 63.4%, and relieved 28.2%. They used the Olshausen operation, in which the uterine ends of the round ligaments are stitched to the anterior abdominal wall. Hurd (1927) (1,000 cases in five and a half years, done by many different methods) found 88% successes in the whole series, both anatomical and symptomatic, with 12% failures. The purely anatomical successes were 96% for the whole series. He found that the Gilliam operation was the best for curing abdominal pain and backache but was not of very much value for sterility. Abdominal pain was the most frequent symptom remaining after operation. Gardner (1935) (145 cases), using a combined technique

of shortening the utero-sacral ligaments followed by the Baldy-Webster operation, reports 85% complete relief both anatomically and symptomatically. Two patients, however, died of pulmonary embolism, and only 11 became pregnant afterwards. Wollner (1932) (100 cases), using a modified Gilliam operation, reports an "excellent result" in 65%, but he does not say whether they were an anatomical success. He points out that pain in the back is usually not relieved by operation; and, in fact, it should always be explained to the patient that her symptoms may be no better afterwards. He particularly stresses the bad psychological effect of wearing a pessary, but points out that this should always be tried first to see if the symptoms are any better when the uterus is anteverted. Falk (1937) in America and Fletcher Shaw (1931) and Luker (1931) in this country all agree that a pessary should be tried first, at least for a year. Sharman (1932), reporting from Glasgow, says that he uses several methods, including the extraperitoneal Gilliam operation, the Baldy-Webster, and the anterior shortening of round ligaments. He finds that the Gilliam gives an anatomical cure in 93%, with 87% showing a symptomatic cure also. The anterior shortening gave subjective success in 66.7%. He found that after pregnancy the uterus reverted to its old position in 14% of his cases, and 25% of patients operated upon for sterility subsequently became pregnant. Salmond (1935), at the Royal Free Hospital, using the Mayo modification of the Gilliam operation, reports 24 "good results" out of 32 cases seen.

Since this article was completed Charles (1940), in London, reports only 2 failures in the anatomical sense out of a series of 98 cases examined, but quite a number of symptomatic failures. He found that dyspareunia could be cured as a rule, but menorrhagia, backache, and dysmenorrhoea often remained.

Present Series

In this series followed up in Bristol there were altogether 120 patients operated upon for backward displacement of the uterus between the years 1930 and 1937 inclusive. All these were written to and asked to attend for examination if possible; 92 did so, and 6 wrote letters. Practically all the patients were between the ages of 18 and 40 years at the time of operation. Of the 92 who were re-examined 4 were single and 88 married. Nearly all were sent up by their own doctors from both town and country practices because of their symptoms, which were the usual ones associated with the condition—namely, backache, abdominal pain, either left- or right-sided, menstrual disorders usually in the form of menorrhagia, dyspareunia, or vaginal discharge. Every patient had one or several of these symptoms. It was found that lower abdominal pain is an even more common symptom than the time-honoured backache. None of these patients had tried wearing any pessary before operation, nor had any had a baby less than twelve months previously. Neither had any patient been investigated by the orthopaedic department: it was presumed, rightly or wrongly, that the symptoms were caused by the retroversion.

Other patients were sent up by their doctors for sterility, with or without other symptoms; of these, 19 reported. There was a further small group of patients upon whom operation was performed because of repeated abortion, which was thought to be due to the retroverted uterus.

Operation.—The operative technique used in every case was a simple one. A preliminary dilatation and curettage was performed, and the abdomen was then opened by a curved transverse incision just above the symphysis pubis, which would later be covered by the pubic hair. The uterus was identified and the round ligaments were short-

ened by means of medium linen thread—a running stitch going from side to side the length of each ligament. The two ends of the thread were tied firmly so that the round ligament was plicated. Another stitch was then put through each fold of the plication and tied over the top to ensure firm anchorage. If the ovaries were found to be prolapsed they were suspended by shortening the ovarian ligaments, and any small retention cysts were pricked. All the patients made a good immediate recovery: there were no post-operative deaths and no complications.

Results

In studying the end-results it must be noted that every patient seen had been operated on at least three years previously, some as long as seven years. It was found that the cases could be divided into definite groups. First of all there were those which had a perfect anatomical result, the uterus being well anteverted, ovaries not prolapsed, and all symptoms cured; these formed exactly 50% of all the cases seen.

The second group comprised those patients in whom the anatomical result appeared perfect but in whom certain symptoms still remained or new symptoms had arisen since operation. This group contained 27 patients, or 29.3% of all those seen. The main symptoms were backache, pain in the lower abdomen, and menstrual disorders. Complaint was often made that before operation the pain was on the right side, whilst now it was on the left, or vice versa. Eight patients complained of vaginal discharge, mostly leucorrhoea, 5 of dyspareunia though the ovaries were not obviously palpable, 2 had "bearing-down" pains, and 3 had urinary symptoms. It is obvious that many of these complaints have a psychological aspect, and it is well known that once some women's attention has been drawn to their urogenital organs they always tend to have trouble there; in fact, they are not grateful even if cured. However, taking both these groups as a whole, there was a perfect anatomical result in 79.3% of cases.

There was a third, rather strange, group of patients who came up very happily and reported that they had been perfectly well since the operation and that all their symptoms had gone. One or two even brought bunches of roses as a token of gratitude! However, on examination it was found with regret that the uterus had gone back to its old position and was still retroverted. There were 8 cases in this group, or 8.7% of the whole. Naturally these women were not told what had happened, and they went away very pleased. Here, again, either there must be some psychological factor helping to produce a cure or else the mere fact of the uterus being retroverted does not necessarily cause all the symptoms that are attributed to it. There must be some additional factor for their discomfort, but it is not always clear what this factor is. It is well known that a retroverted uterus may be discovered in an unmarried girl that gives rise to no trouble at all; therefore, why should the mere fact of retroversion necessarily cause all these symptoms in the married woman?

The fourth group consisted of 11 cases which were counted as failures. In 7 of these the uterus had reverted to its old position and the symptoms were still present or were multiplied. In 4 some other condition had arisen (fibroids in 2 and severe bleeding in 2) that necessitated a hysterectomy.

It was interesting to note that altogether 21 patients had normal pregnancies after the operation, and in 17 (90.4%) the uterus was still in a good position after delivery, and there were only two known failures.

Lastly, there were the 19 patients who were operated upon mainly because of their sterility, 11 (57.9%) of whom subsequently became pregnant. As compared with other

results this is a very high proportion, as 50% seems to be the highest figure recorded. Of the three patients treated for repeated abortion two did not have any more abortions.

As stated, six patients wrote and reported their condition. However, as the position of the uterus was not known they are not included.

The Question of Operation

Now, having seen these results, the question arises, What is the general practitioner to do with the patients who come to him with symptoms that are associated with a retroverted uterus? Should he advise operation or not? If possible a pessary should always be tried first, and if it relieves the symptoms the operation will probably be a success. However, some patients refuse to wear one; and sometimes the use of pessaries has a bad mental effect and may upset marriage relations. If the main trouble is backache, particularly if associated with retroversion following on a recent labour, the patient should, if not relieved by a pessary, be examined by an orthopaedic surgeon, as in many cases the trouble is not due to the retroversion at all but to temporary functional muscular insufficiency, or a true traumatic backache caused by injury to the pelvic ligaments or lower lumbar vertebrae at delivery. These factors are often overlooked. However, if the patient wishes it, the operation for replacing the uterus may be advised, but it should always be explained that it may not be successful, particularly if she gets no benefit from a pessary.

Why the operation is a failure in so many cases is an interesting speculation. Probably the anatomical failure is due to the fact that the round ligaments are not really strong enough to hold the uterus in position without some additional support, particularly if it is somewhat bulky. The symptomatic failures are no doubt due to the fact that these women believe the retroversion to be the cause of all their troubles, when actually these are due to some other factor, either organic or functional. Clare (1933) suggests that if at operation the uterus is seen to be congested it is very likely the source of the trouble, but if it is of normal colour the malposition is probably of no importance, and the symptomatic results will be poor. He therefore makes all his patients walk about before operation, and has them anaesthetized in a semi-sitting position in order to produce natural living conditions.

However, in cases of sterility or repeated abortion for which no other cause can be found in either the husband or the wife the practitioner is quite justified in pressing operation, as there is a reasonable chance that a successful pregnancy may result.

Summary

In 120 patients operated upon for backward displacement of the uterus between 1930 and 1937 it has been found that only 50% gave a result that was perfect both anatomically and symptomatically.

Practitioners are therefore advised to look for some other cause for the symptoms, either functional or orthopaedic.

A pessary should always be tried before operation is suggested.

In cases of sterility for which no other cause can be found, operation gives a reasonable chance of success.

I am grateful to Prof. Drew-Smythe for allowing me to publish these figures.

A SIMPLE OPERATION FOR REDUCTION OF FRACTURES OF THE OS CALCIS

BY

WALTER GORDON CAMPBELL, F.R.C.S.

Surgeon Lieut.-Commander, R.N.V.R.; Assistant Surgeon,
 Dundee Royal Infirmary; Clinical Lecturer in Surgery,
 St. Andrews University; Surgical Specialist, H.M.
 Hospital Ship

Fracture through the waist of the os calcis is still the "unsolved fracture," and brave is the man who claims any great measure of success in its treatment. Surgical literature abounds with papers dealing with results and methods of treatment, but, as McFarland pointed out, the disability resulting from this fracture, as revealed by statistics from various insurance companies, shows that skill and experience seem in no way to guarantee a better result than can be attained by unspecialized treatment.

The numerous methods employed in its treatment serve to confirm the statement that this fracture is still "unsolved." During my relatively short career as a practitioner of the surgical art I have turned from one mode of treatment to the other in dealing with these fractures. At one time fixation in plaster-of-Paris was used, without any attempt at reduction; then came the dreadful procedure of "pulverizing" the fractured bone and moulding it somehow into shape; then active skeletal traction was employed to pull down the elevated posterior fragment; then Böhler showed that lateral compression would reduce another factor in the displacement. All our results seemed poor, and American surgeons advocated immediate fusion of the subastragaloid joint, essentially on the grounds that conservative treatment is merely a waste of time, as almost all cases develop subastragaloid arthritis and will require fusion anyhow. But even after obliterating the various adjacent joints we became all too familiar with the patient with the shuffling gait and the painful foot who haunted our massage and out-patient departments and made the hours we spent there a misery, and for whom nothing could be done.

In spite of these setbacks we cannot admit defeat. These fractures are becoming more and more common as the speed and height at which we live increase, and we must accept the challenge to find some certain cure for them, just as we have done for so many others which were formerly associated with such poor results. We have mastered the treatment of the Colles and many other articular fractures, and there is no reason why good results should not be obtained in fractures of the os calcis.

The results which have been attained in Colles's and other para-articular fractures have shown that the secret of success lies in anatomical reduction. But this reduction must be carried out early. We have learnt to regard the Colles fracture as a surgical emergency, as urgent as, or more urgent than, an acute appendix; for we have found that joint stiffness and its complications, pain and atrophic bone changes, can be avoided by early anatomical reduction. Our attitude to fractures of the os calcis is entirely different. If admitted to hospital late in the day they are lucky if they are even radiographed, and if reduced within a short period of the accident the patients must consider themselves extremely fortunate. I do not discount the zeal or efficiency of those treating them. We have been brought up to look on these fractures as pretty hopeless, and have, too, been habituated to "delayed" methods of reduction (skeletal traction, for instance, taking days to reduce the deformity), and so do not realize that "such fractures are dangerous."

At the present time many fractures of the os calcis must be treated without proper equipment, and for this reason, too, a simple operation will be described which successfully reduced a fracture we had failed to reduce by skeletal traction. The equipment needed is minimal, and the ease and the simplicity make it suitable for use by persons with no special surgical skill.

Case Report

An aircraftman in the Fleet Air Arm, aged 22, fell twenty-five feet on November 21, 1940, and landed heavily on his left foot. On admission to a hospital ship he was found to be suffering from compression fracture of the left os calcis, with severe comminution and gross upward displacement of the posterior fragment.

First Operation.—On November 22, under pentothal and spinal anaesthesia (Dr. R. F. Woolmer), a Steinmann pin was inserted through the soft tissues above the posterior fragment, behind the ankle. By means of this, screw traction was carried out with a Watson-Jones lower-leg-fracture traction apparatus. While full traction was maintained, lateral compression of the fracture was effected by means of the handles of a pair of Stille's plaster shears, used like a nut-cracker. When reduction was thought to have been effected the limb was plastered and the Steinmann pin removed.

Radiographs, however, showed that reduction had not been attained. The fracture was so grossly displaced that it could not be left as it was. We had two alternatives: continuous skeletal traction by means of a Kirschner wire through the posterior fragment, or immediate fusion of the subastragaloid joint. A Kirschner wire seemed unlikely to succeed any more than a Steinmann pin, and arthrodesis was dangerous on account of the fear of sepsis with the unhealed wounds present from the Steinmann pin. The simple procedure described below was therefore carried out.

Second Operation.—On November 28, under pentothal and spinal anaesthesia (Dr. R. F. Woolmer), a small incision was made over the posterior surface of the os calcis, and into this a strong Steinmann pin was inserted forwards through the body of the posterior fragment until the point was judged to be at the fracture through the waist of the bone. The handle of the pin was then rotated in a plantar direction, the effect being to

Discussion

It is obviously impossible to discuss the method on one successful case, especially as I was unable to follow up the patient; but the simplicity of the procedure and the few instruments needed for its performance—especially at this time when many fractures must be treated in hastily equipped hospitals—justify publication.

The reduction clearly showed that descent of the anterior part of the posterior fragment is a factor in the displacement that has not been sufficiently recognized. It is difficult to see how simple traction on the posterior part of the fracture can be as successful in reducing this displacement as the torque force applied by a pin passing through the fragment.

By this method immediate and full reduction can be obtained safely, and no special skill or knowledge is required to carry out the operation. A carpenter's chest supplies accessible instruments which could easily be substituted for the Steinmann pin and the Stille shears. It is true that a simple closed fracture is rendered compound by the method, but our experience in all varieties of fractures shows that little is to be feared from this unless some foreign body, such as a plate, is left at the site of fracture.

Summary

A simple operation for reduction of fractures of the os calcis has been described which requires the minimum of equipment and of surgical skill.

Attention has been drawn to the downward displacement of the anterior part of the posterior fragment and to the ease with which it can be elevated into position.

The operation seems so obvious that I fear it may have been previously described. I can find no record of it, but if there has been I would offer my apologies.

Medical Memoranda

Traumatic Rupture of the Pectoralis Major

Although traumatic rupture of a muscle or tendon is by no means uncommon, the following case is thought to be worthy of record as I have been unable to find any previous description of the pectoralis major being so affected.

CASE REPORT

The patient, a miner aged 47, of excellent physique, sustained a severe blow on his right shoulder whilst working in the pit on February 6, 1941. He was knocking out some pit props when a large piece of stone, weighing approximately 25 cwt., struck his right upper arm a glancing blow; at the moment of impact the arm was in the position of abduction and external rotation. He immediately experienced severe pain in the right shoulder and right upper arm, and was subsequently unable to move the arm. After a few hours considerable swelling of the shoulder was noticed; this was followed by bruising, which soon became severe, over the anterior aspect of the shoulder-joint, the anterior axillary fold, and the upper half of the right arm. The patient attended the casualty department the same day, but a radiograph of the shoulder-joint and upper arm revealed no bony injury. He was not seen again until March 4, when he attended the surgical out-patient department complaining of a painful and weak right shoulder. He stated that he had been unable to move his right arm for six days after the accident and that he was gradually getting back the use of the arm, but that it still felt weak. He had recently noticed that his shoulder muscles "had gone to nothing."

On examination the left shoulder and arm were normal, the muscles being well developed. The right shoulder region presented a most striking picture. There was pronounced "hollowing" over the anterior aspect of the chest wall on the right side, the anterior axillary fold was absent, and the upper ribs were

FIGS. 1 AND 2.—Diagrams showing reduction of fractured os calcis by means of a Steinmann pin. These are exaggerated to show the torque effect produced by depressing the handle of the Steinmann pin.

lever down the posterior part of the fractured bone and at the same time to elevate the anterior part. The patient was then taken to the x-ray department, with the pin still in situ, and the movement carried out under the screen, when it could be clearly seen that depression of the handle produced a "torque" effect on the fracture, the posterior part being depressed and the anterior part being elevated into its proper relation with the astragalus. Very little force was needed to bring this about, and full correction was easily obtained. A plaster cast was then applied around the fracture, which included the pin, the foot being in plantar flexion. We intended to leave the pin in position, fearing redisplacement, but when the cast had hardened it was found that there was no strain on the pin, which was accordingly removed.

Radiographs taken two days later showed no displacement of the fragments, and the patient was allowed to return to his ship.

unduly prominent. On attempted active contraction of the affected pectoralis major it was at once obvious that the whole of the sterno-costal part of the muscle had been ruptured at its musculo-tendinous junction, some 2 inches from its insertion into the lateral lip of the intertubercular sulcus of the humerus. The divided ends were easily palpable; they were widely separated, the main mass of the muscle being bound down to the inner aspect of the chest wall in the region of the sternum. The tendinous insertion could be felt to be comparatively freely movable, but the muscle itself had become firmly adherent in a contracted position and could not be moved apart from its surrounding structures. There was a gap of approximately 5 inches between the two ends, as measured with the arm to the side. There was at this time no external evidence of trauma, no swelling, and no bruising, and the patient stated that the pain steadily decreased as he regained the use of the limb. The movements of the shoulder-joint were almost full and were accompanied by relatively little pain. There was some weakness of adduction and internal rotation of the arm as compared with the normal side, but this was not unduly marked.

DISCUSSION

The following points are of interest:

1. The rarity of complete traumatic rupture of the sterno-costal head of the pectoralis major. The muscles and tendons usually ruptured by trauma are the quadriceps extensor cruris, the adductor longus, the tendo Achillis, and the plantaris in the lower extremity, and the supraspinatus and biceps in the upper extremity. The rectus abdominis may also be ruptured, but this is usually in association with the convulsions of tetanus.
2. Despite the fact that the blow was undoubtedly a very severe one the humerus suffered neither a dislocation of its head nor a fracture of its shaft, the pectoralis major alone being torn. The site of the rupture was at the junction of the muscular and tendinous portions, this being the usual place for such a rupture to occur.
3. The mechanism of this particular injury would seem to have been a sudden involuntary contraction of the muscle against a severe wrench which forced the arm to take up a position of extreme external rotation and abduction.
4. That a negative radiograph of the shoulder-joint may lead the unwary into a sense of false security, and the pronounced swelling be put down to simple though severe bruising. Looking back on the case the symptoms were quite characteristic. At the time of the initial injury the patient experienced a sudden sharp pain at the site of rupture of the pectoralis major, though he was not aware of "something having snapped," as is often the case. This was followed by loss of function of the affected part, which in turn was followed by severe swelling, accompanied by ecchymosis. As the swelling subsided the patient noticed a gap between the two retracted ends of the muscle and somewhat naturally assumed that his shoulder muscles were "wasting away."
5. That active movements of the arm were very good and after four weeks were almost painless. The power of the arm was relatively little impaired, adduction and internal rotation being carried out mainly by the teres major, subscapularis, and the latissimus dorsi.

As regards the subsequent treatment it was obvious that at the time the condition was diagnosed no surgical measures could be undertaken with any hope of success. The muscle ends had retracted widely and the sterno-costal portion had become firmly adherent to the inner half of the chest wall, leaving a gap which could not be successfully bridged.

It is usually agreed that primary suture of a torn muscle should be undertaken within the first five or six days of the injury, and that secondary suture, even if the ends can be approximated, usually yields a disappointing result, owing to the undue amount of fibrosis present and to the adhesion of the divided muscle ends to the adjacent structures. It is more than likely that an unsuccessful attempt to suture the muscle in the above case might well have led to considerably more disability than at present exists, and in this connexion it is worth recalling that rarely do patients following on a radical amputation of the breast complain of weakness in the affected arm, though it must be admitted that these patients are not engaged in heavy manual work.

I wish to thank Mr. H. Blacow Yates, honorary surgeon to the Royal Hospital, Sheffield, for allowing me to publish this case.

 Surgical Registrar, the Royal Hospital, Sheffield.

Reviews

THE LYMPHATIC SYSTEM

Lymphatics, Lymph, and Lymphoid Tissue: Their Physiological and Clinical Significance. By Cecil Kent Drinker, M.D., D.Sc., and Joseph Mendel Yoffey, M.Sc., M.D., F.R.C.S. (Pp. 406.) Massachusetts: Harvard University Press, 1941.

Whether war advances or retards the progress of science is a problem which many have debated during these last two years without coming to agreement, but there can be little doubt that it accelerates the practical application of new knowledge. The problems raised by war injuries, whether from toxic gases, burns, trauma, or shock, have forced clinical workers to modernize their intellectual and technical equipment and to realize that names like Rous, Menkin, Adrian, and Florey should mean as much to surgeons as Robert Jones, the Mayos, Harvey Cushing, or O'Shaughnessy. At first sight this technical monograph on the lymphatics by Drinker and Yoffey might be regarded as suitable only for the physiologist, the experimental pathologist, or the haematologist. In reality it contains more of value for the thoughtful physician and surgeon than the numerous primers on war medicine and surgery which are considered appropriate for them. It is by no means easy reading, and it would have been better for the general reader if a dogmatic summary had been appended to each chapter.

The book begins with a description of the anatomical and physiological organization of the lymphatic apparatus. In the lower vertebrates the lymphatic vessels and the lymphoid tissue are completely separate, and it is only in the higher mammals that we find an intimate association of lymph nodes and vessels, such that lymph never reaches the blood without passing through at least one lymph node. On the other hand, in all vertebrates there is a close association between lymphoid tissue and the alimentary tract. The function of the lymphatic vessels is obvious. They return to the blood stream the fluid—including protein, particulate matter, and cells—which has filtered through the blood capillaries and is unable to re-enter them. The agencies in this flow, which is greatly increased in inflammation, are the tissue tension and the active and passive movements of the part. The function of the lymphoid tissue is much more obscure. It is true that the nodes act as filters, but they are mechanically less effective against viruses than against larger particles and bacteria. Any barrier action of the lymph nodes is more than offset by the dangerously rapid extension of disease that lymphatic vessels render possible, and the organisms are excluded from the action of antibodies which are of high molecular weight and unable to pass from the blood capillaries into the lymphatic system. "It appears from Menkin's work that in a focus of bacterial inflammation the exclusion of bacteria from the lymphatic vessels is much more to be desired than that they should enter and be transported rapidly to the regional nodes." Hence the superiority of chemotherapy by diffusible drugs such as the sulphonamides. The function and fate of the lymphocyte remain a complete mystery. Although lymphocytes survive for several days *in vitro*, enough cells are passed into the blood stream every day to replace the circulating lymphocytes two or three times over. What happens to them all? Yoffey thinks they go to the bone marrow to be the precursors of the red cells and granular leucocytes, but his arguments are not altogether convincing.

The book ends with a chapter entitled "Practical Considerations," but throughout the volume the clinical reader

is continually coming on information which is directly useful in his work and which frequently upsets old or preconceived ideas.

HEART FAILURE

Heart Failure. By Arthur M. Fishberg, M.D. Second edition, thoroughly revised. (Pp. 829; illustrated. 40s. net.) London: Henry Kimpton. 1940.

A second edition of Fishberg's *Heart Failure* has appeared only three years after the original publication. Some additions have been made in most chapters, resulting in a slight increase in size of the already long book, but on the whole the text is not very much altered. More than is the case with most books for the clinician the subject is treated as a study in abnormal physiology, and recent work on the circulatory variables such as cardiac output, blood volume, and venous pressure is reviewed. The traditional method of describing diseases on an aetiological classification in which a discussion of the symptoms of each type forms a part is largely reversed, each symptom being taken separately and then its possible causes given. This method is natural when the subject is treated from the functional rather than from the anatomical point of view. It is not enough now to speak of heart failure simply, and the precise form, of which there are several, should be recognized. These various forms of heart failure are considered in detail. A good account of peripheral circulatory failure and shock is given. This sometimes results from heart disease, though more often from other causes, of which the common traumatic form is of paramount importance to-day. A section on treatment completes one of the best works yet published on circulatory disease.

DYNAMIC HYGIENE

Effective Living. By C. E. Turner, A.M., Sc.D., Dr.P.H., and Elizabeth McHose, B.S., M.A. (Pp. 432. 10s. net.) London: Henry Kimpton. 1941.

Health is presumably the "end" of hygiene, but, as Aristotle said, there are many kinds of ends—such, for example, as the end in itself, and on the other hand ends subordinate to some higher and greater end. A few decades ago people in Britain were content to regard health as an end in itself. More recently, breathing the social spirit, we looked to efficiency as the aim to which all hygiene moved. To-day, with a world war upon us, our views on the question have become more dynamic. We realize that the ultimate end of hygiene is not efficiency alone but efficiency well used, which gives power to nations. Thus by reason of the man and woman power of our country we are able to encounter face to face—to quote Aristotle again—"the greatest and noblest danger."

The recent work on hygiene by Professor C. E. Turner and Instructress Elizabeth McHose exhibits to American youth this dynamic aspect of health and all that it implies. *Effective Living*, as the book is called, is expounded in relation first to the individual, then to the family, and finally to the community. "Health," it is urged, "means courage and enthusiasm for life. It is well worth working for, and yet it is not the final aim. Honour, integrity, and the defence of home and country may demand the sacrifice of health and life itself." All the subsequent advice offered, whether physiological, mental, or ethical, appears to us to be thoroughly sound. The numerous illustrations are excellent and often charming, the mosquito alone, which figures twice, receiving less than justice on both occasions. We have found no medical errors in the book. Having regard to the purpose in view the whole field is amply covered. The main issue is never lost sight of, and the authors are to be congratulated upon their competent and high-minded presentation of dynamic hygiene.

Notes on Books

Under the excellent title of *A Doctor Remembers* Dr. E. A. BARTON publishes, after half a century of practice in the centre of Kensington, some very readable reminiscences of his career and his practice, with reflections upon them and on several medical topics of the times. Designed more for the lay public than for his professional brethren, his chapters give a lifelike picture of a really "sympathetic" general practitioner dealing mainly with the more affluent professional classes—academicians, judges, King's Counsel, and so forth. There are many good stories, and much that is entertaining, as well as incidents which may make laymen more understanding than they sometimes are of the difficulties a doctor has to face. It might be wished that his chapter on "medical etiquette" had made it clear that this much-misused term covers a code of professional conduct devised in the interests of patients, not of their medical attendants; but with this slight grumble one can part with Dr. Barton wishing oneself capable of something half as interesting—nor should there be omitted a word of praise for the restraint without which a doctor's memoirs might be more sensational but would not be so creditable to his discretion. The book is published at 12s. 6d. by Seeley, Service and Co.

The popularity of Miss K. C. CLARK's book *Positioning in Radiography* is shown by the publication of a second edition two years after the first. Although some new text has been added and some new illustrations substituted for old, the book is substantially the same in form as before. The second edition is thirty pages longer but contains the same number of illustrations. Two new sections have been added, on x-ray screen photography and serioscopy, and many other sections have been brought up to date. The title of this work does not nearly do justice to its nature. It is much more than a book on positioning in radiography: it is a remarkably complete account of every aspect of that art, and the second edition fully maintains the high standard set by the first. In this respect the purely radiographic parts are more complete and authoritative than those procedures that are more in the province of the radiologist, but the author wisely disarms criticism by advising her colleagues to seek the instructions of the radiologist-in-charge on such matters as, for example, the technique of cholecystography. The second edition is to be recommended with the same confidence as its predecessor. It is published at 63s. by Heinemann for Ilford Ltd.

Preparations and Appliances

NEW VITAMIN PREPARATIONS

The Glaxo Laboratories, Ltd., have introduced two new preparations. Nicorbin tablets contain 1 mg. aneurin hydrochloride, 10 mg. nicotinic acid, and 25 mg. ascorbic acid—that is to say, vitamins B₁ and C, together with the antipellagra factor of the B complex. The manufacturers say that these water-soluble factors are combined for the treatment of subclinical multiple deficiency states, and not merely as a dietetic supplement. The amounts of B₁ and C are certainly satisfactory for normal individuals who take three tablets a day as recommended, but expert opinion is now in favour of larger amounts for those who have any suggestion of deficiency. This is particularly so for nicotinic acid, for Sydenstricker (*Annals of Internal Medicine*, 1941, 14, 1499) states that he administers as much as 600 mg. daily in treatment.

The second preparation is of high-potency ostelin capsules. Each capsule contains 100,000 international units of vitamin D (calciferol) in vegetable oil, which gives the greatest likelihood of maximal absorption. The manufacturers point out that success with large doses of vitamin D has been recorded in arthritis, parathyroid tetany, rickets, hay fever, and asthma. It is interesting to note that the fear of toxic manifestations with so large doses no longer worries those who have had experience in giving them. Signs of nausea indicate that the treatment should be stopped, after which all is well.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY NOVEMBER 8 1941

ADVANCES IN ELECTRO-ENCEPHALOGRAPHY

The scope of electro-encephalography has broadened steadily through the years, and no one can now deny its value, both as a diagnostic aid and as an instrument for neurophysiological research. Progress has been along three main lines: the standardization of technique and the introduction of systematic criteria of interpretation; the investigation of naturally occurring phenomena in both healthy and abnormal subjects; and the study of the effect upon the brain potentials of drugs and other changes in the external and internal environment. Three papers from America are signposts along these main routes of advance. Pauline Davis¹ of Boston has described her methods of classifying records, both normal and abnormal, on the basis of the amplitude and frequency of the rhythmic waves, and the presence or absence of non-rhythmic fluctuations. She also pays attention to the degree of symmetry of the two hemispheres, and to the degree of response of the normal rhythms to mental and visual stimulation. She points out that most of the attempts to devise some measure of electro-encephalographic tracings which will give in one number the total information contained in the record have been abortive and misleading, because the various features concerned do not fall into the same class of phenomena and are therefore incommensurable. It would clearly be of the greatest value if records taken by any investigator could be described in accepted terms and compared with tracings from any other source, but to make this possible in the present state of the subject would mean much regimentation, which would be highly obnoxious to those who approach the subject from a physiological standpoint.

To reach a compromise between dictated order and individual disorder is one of the most urgent tasks which confront electro-encephalographers, both in this country and elsewhere. It is clear that to make every examination comparable with every other a very large number of records must be taken of each patient, whether their condition is "interesting" or "uninteresting"; at least a dozen separate records would have to be made in standard conditions, each would have to be accurately measured, and some would have to be analysed for harmonic content. There is no centre in this country with sufficient staff or time to work along these lines, and like all other theoretical perfections this will undoubtedly be adulterated according to the mood and taste of the investigator. When communications become

easier an international congress of those interested in electro-encephalography would be most desirable, and would undoubtedly bring forth valuable and interesting decisions.

In the very early days of electro-encephalography Adrian commented that the normal records were "disappointingly constant," meaning that the administration of drugs and changes of the surroundings and condition of the subject within the physiological range produced very little detectable change in the records from the head. Fowler² of Iowa has studied the effect upon the electro-encephalograms in normal and mental subjects of adrenaline, mecholyl, cocaine, and sodium amytal, measuring also the rheobase, chronaxie, and other electrical properties of the muscles. Very little effect was obtained with adrenaline, mecholyl, or cocaine. What changes there were could be correlated slightly with the subjective impressions of the patient, but no satisfactory relationship was established. Sodium amytal, which caused noticeable psychological changes in all cases, gave rise to the well-known slowing of the cortical rhythms produced by most anaesthetics. Also the normal alpha rhythm—the presence of which indicates physiological rest in the brain—tends to be augmented by sodium amytal. A great many other experiments have been reported on these lines, and in general only the known anaesthetics and changes in hydrogen-ion concentration seem to affect the cortical rhythms at all dramatically. Anoxia within the physiological range is relatively without effect, but when it goes so far as to induce changes of consciousness or behaviour it is associated with the usual non-specific slow rhythms which Walter called delta waves when describing their appearance near cerebral tumours. The appearance of such slow electrical rhythms is still the chief diagnostic abnormality, and, from the frequency with which it occurs in quite different conditions, we must assume that it is a non-specific indicator of cerebral distress, dystrophy, or degeneration.

A communication by Usher and Jasper³ of Montreal shows how useful electro-encephalographic studies may be in investigating symptoms even in diseases that are not strictly neurological. The involuntary movements in Sydenham's chorea have been generally looked upon merely as part of the syndrome of rheumatic fever, but no one has explained exactly how the rheumatic process is concerned in the aetiology of the condition. Pathological studies of patients with this complaint are rare, for they usually recover; but such evidence as is available shows changes which have also been described in other acute infectious diseases, such as degeneration in the basal ganglia. There is no evidence of a specific local lesion characteristic of patients with chorea. Usher and Jasper's work on twenty-three children with Sydenham's chorea reveals that in all cases with severe symptoms prominent generalized abnormalities occur in the electro-encephalogram. These abnormalities are either a decrease or an absence of the normal alpha rhythms, or the presence of the usual delta waves. Mild cases showed no significant departure from the normal range, and in general the degree of abnormality

¹ *J. exp. Psychol.*, 1941, 23, 37.² *Canad. med. Ass. J.*, 1941, 44, 365.³ *J. Neurophysiol.*, 1941, 4, 92.

of the electro-encephalogram correlated well with the severity of the symptoms. Moreover, clinical improvement was associated with corresponding improvement in the electro-encephalogram, and a persistence of electro-encephalographic abnormalities during a remission suggested a bad prognosis, as in all these cases the movements returned later. Investigation of the siblings of patients with chorea showed a high proportion of similar abnormalities even when there was no history of chorea except in the original patient, and Usher and Jasper accordingly suggest that chorea may be considered a symptom of cerebral disorder as definite as epilepsy and, like epilepsy, of varied aetiology. One may go even further and speculate whether the symptoms of chorea occur only in those possessing a genetic tendency to such disorders as are accompanied by involuntary movements associated with abnormal electrical properties of the cerebral neurons. A large proportion of "behaviour problem children" also show electro-encephalographic abnormalities, and it is possible that this abnormality is a sign of an inherited or congenital defect rendering the patient liable to either clinical epilepsy or chorea or disturbances of behaviour, according to the influences which happen to be present during their early life. Such a conjecture should provide food for thought for neurologists, psychiatrists, and those interested in heredity and eugenics.

A NATIONAL WAR FORMULARY

Insistence on economy penetrates everywhere in wartime, even to the prescribing of medicines. Not the pill, as a rule, but the sugar coating has to be sacrificed, and even the pill itself may have to be supplied in smaller numbers and of slightly different composition. Sugar is wanted for other purposes, and therefore confections and lozenges must disappear and syrups be restricted to linctuses and to mixtures for children. Animal and vegetable oils and fats, which are needed for food and other vital purposes, are employed in the preparation of liniments, ointments, and lotions, and these, therefore, must be used sparingly. Preparations containing glycerin must so far as possible be eliminated. The strictest economy must be practised with liquid paraffin. Potassium compounds should be prescribed only where the corresponding sodium ones are not satisfactory. These limitations are imposed because important substances ordinarily used in medicinal preparations are now more urgently needed for other purposes. Even if the drugs themselves are still readily available, their packing and distribution make demands on materials, labour, and transport, fully justified if the drugs are essential to medicine, but not if they can be withheld without serious therapeutic disadvantage. Economy as a principle commands universal agreement. To adjust domestic and professional habits to an economy basis is another matter. Long usage makes it difficult for the doctor to reconcile himself to any modification in prescribing, and, prescriptions being given singly and the ingredients ordered in grains and minims, he is apt to ask himself as he writes each one

how a minute economy can possibly be of value, while his overriding consideration—and most rightly—is the good of his patient.

Some time ago the Medical Research Council issued War Memorandum No. 3, prepared by the Therapeutic Requirements Committee, on "Economy in the Use of Drugs in Wartime," and this has now been usefully followed by the *National War Formulary*, the work of a committee appointed by the Minister of Health at the beginning of the present year. The chairman of this committee is Dr. Philip Hamill, who represents the Royal College of Physicians, and its members include representatives of the Ministry of Health, the London County Council, the British Pharmacopoeia Commission, the Therapeutic Requirements Committee, certain pharmaceutical organizations, the voluntary hospitals, and the British Medical Association, the last-named represented by Dr. E. A. Gregg and Mr. Lewis Lilley. Dr. Gregg is chairman and Mr. Lewis Lilley a member of the Insurance Acts Committee of the Association, which, some time before the war and with no thought of war prescribing in mind, produced a formulary for national health insurance purposes, and this has been taken as the working basis by the Ministry of Health Committee. The committee consulted also the pharmacopoeias of the London County Council and of the larger hospitals. The result is a workmanlike compilation which will no doubt be adopted for use in panel practice, and might well be adopted also by hospitals and public bodies in place of their peacetime formularies. To private practitioners, again, it is commended as a *vade mecum* of advice, suggestion, and instruction in wartime practice.

The *National War Formulary*, which is summarized on another page, may be said to represent a return to simplicity. Though it includes new drugs and preparations such as the sulphonamides, vitamins, and antiseptic dyes, it maintains the prominence of some of the older drugs which there may have been a disposition to neglect, not through lack of merit, but because of changes of fashion and of the multitude of new preparations that have appeared on the market. The use in wartime of many familiar compounds is discouraged, yet the range is believed to be sufficient to meet ordinary therapeutic requirements. The most valuable and frequently prescribed preparations have been retained, perhaps with some modification, non-essentials have been eliminated, and alternatives have been furnished where this is practicable and where economy would be effected. The list of mixtures alone runs to close on sixty; of tablets to over forty; of ointments to over twenty; of lotions to fifteen; of emulsions to nine. Of cardrops, nasal douches, mouth washes, eye lotions, gargles, enemas, liniments, sprays and vapours, pastes, paints, and powders there is enough variety to satisfy the most fastidious. A Children's Section is included in which, among other preparations, further mixtures are given, in some instances the same as in the General Section but in smaller doses.

The *Formulary* is suggestive and advisory. The doctor may still order what he likes, in so far as it is available, and there is no authority for dispensing substitutes for drugs specified by the prescriber, though a

certain discretion may be allowed as to the form in which they are made up. For example, a pharmacist out of stock of certain pills may dispense equivalent tablets, but he must state on the prescription if tablets have been supplied. The good sense of the medical profession can be trusted to accept the *Formulary* as a wartime expedient which may have in certain respects permanent results on prescribing. It brings about no revolution, but it does offer medical men and women an opportunity, with the minimum of inconvenience to themselves or disadvantage to their patients, to fall in with certain reasonable requirements and limitations arising out of the national necessity.

HEALTH IN PARLIAMENT

The debate in the House of Commons on October 21, fully reported in the last issue of the *Journal*, was a welcome sign that our legislators are showing an interest in what should be the most important matter in the life of the nation—namely, the health and well-being of its citizens. The debate centred on two main issues—the hospital services of the country, and special instances of sickness in the population. Dr. Howitt, who opened the debate, expressed his pleasure with the Minister of Health's statement on Government hospital policy, and his sentiment was echoed by other speakers. Captain Elliston, for example, welcomed the Minister's decision to put upon the local authorities the responsibility for securing adequate hospitals. He mentioned that up to the end of June the damage done to hospitals exceeded in value £20,000,000, which lends force to his argument that the survey of hospitals now to be undertaken must be entrusted to persons with "open minds and wide experience, with no axe to grind for any vested interests or established systems." As Sir Frederick Menzies points out in a letter at page 666, the Minister's policy has had a very good press, but many people would seem to have missed a fundamental point in this policy to which we drew attention in a leading article on October 18 and which is discussed more vigorously by Sir Frederick this week. Any discussion, therefore, of the merits or demerits of the voluntary or the municipal hospitals must in future be carried on in the full awareness of the financial control that will be exercised by the major local authorities over voluntary hospitals. It is one thing to rejoice sentimentally over the happy partnership between the two systems which is so confidently foretold by those who, like Pangloss, are sure that the best of all possible worlds is on the doorstep. It is more salutary, perhaps, to recognize that there are sharp cleavages of opinion and conflicting vested interests, and that in the long run he who holds the purse will see that the tune is played to his liking. Mr. Messer, Labour Member for Tottenham South, in a speech which showed his very real interest in the wider aspects of health problems, said that there was in this country neither a voluntary hospital "system" nor a municipal hospital "system." He was severely critical of the voluntary hospitals, saying that each one was a law unto itself and acted quite independently of others, and that the time

had come when both types of hospital should be re-planned more comprehensively than was outlined in the Minister's speech. He was in favour of dealing with the matter somewhat on the lines of education, in which under the Board of Education there were standardized salaries for teachers throughout the whole of the country. "The truth is," he remarked, "that the voluntary hospitals cannot continue." His condemnation of the voluntary hospitals received support from a medical Member of Parliament, Dr. Edith Summerskill, who began by saying that she intended to devote most of her speech to "condemning the present system root and branch."

The other side of the question was put most cogently by Sir Francis Fremantle and Prof. A. V. Hill, both of whom took into account not only the virtues of the voluntary hospitals but also the fact that in this country we prefer evolution to revolution. Sir Francis put the matter in a nutshell by posing this question: "What are the needs of the nation, and how can we make best use of the facilities and equipment available at the present time?" He pointed out that it was a comparatively new departure for the State to take over the social services and the social care of the people, and applauded this as a proper development. The emphasis is on development. The old tradition, he said, was useless without the modern spirit, but the modern spirit was also useless without the old tradition. He admitted that many voluntary hospitals had outworn their day, and believed that some kind of interference by the State in the management of the voluntary hospitals was necessary. He did well, too, to stress the deficiencies of the municipal system, and asked what was the value of local elections when very often only 30% went to the poll. "What," he asked, "is the real advantage if the management is elected on any qualification except that of their capacity for the work?"

Professor Hill, who spoke as one who was no "upholder of the privileges of the medical profession," raised the level of the debate by concentrating upon certain general principles, and deplored any attempt to rush in and try to build up a system without careful thought and experiment. The important thing in medicine, he remarked, was to experiment, and he advocated that the two "systems" should be allowed to develop side by side so that the good should be found out and the bad discovered and discarded. In this way we would progress as animals have progressed and as our social system has progressed—by evolution. Evolution is essentially compromise—a continuing compromise between the animal and his environment; and the gift for compromise is one of the most salutary qualities this country possesses.

One of the special aspects of disease that was brought to light in the House of Commons was tuberculosis. Dr. Howitt believed that at the beginning of the war a great mistake had been made in evacuating so many cases of tuberculosis from sanatoria to their homes, and stressed the danger to those in contact with the returned cases. Mr. Messer forcibly underlined these observations by pointing out that in the first two years of this war the deaths from tuberculosis had gone up by 2,000. A recent survey in two areas, he said, had shown there

were 21 new cases in the age group 11-20 in the first quarter of 1939, and the figures for the corresponding quarters of 1940 and 1941 were 28 and 35 respectively. In the age group 21-30 the numbers of new cases in the first quarters of 1939, 1940, and 1941 were respectively 34, 42, and 65. If there were not sufficient accommodation, then he suggested that the big mansions and houses of the country should be conscripted to provide the necessary beds. Major Haden Guest drew attention to the article by Drs. Laidlaw and Macfarlane in the *British Medical Journal* of September 27, in which the increase in the number of cases of tuberculosis was attributed to a combination of long hours, overtime, strain, and ill-spent leisure, and suggested that "we are not using our great public health organization at the present time to avoid increase in that kind of disease." The Minister of Health said that the figures given by Mr. Messer were not borne out over the whole field, and that when the figures for the first quarter of this year were available a reduction of 7% would be found as compared with the first quarter of 1940. He said, too, that he proposed to do his best to meet the need for beds, and pointed out that they were up against a problem not only of beds but also of nurses. Among figures given by the Minister perhaps the most important was the new low record of the maternal death rate of 2.61 per thousand for 1940, and this he attributed generally to the wartime maternity hospitals set up in the reception areas, in which nearly 30,000 babies have been born during the war. On the general subject of the health of the nation, the Minister paid a very warm tribute to the work that is being done in liaison with the Ministry and other bodies by the Central Council for Health Education, and drew the attention of the House to a number of pamphlets and leaflets on health matters prepared by the Central Council for distribution to the ordinary man and woman in the street.

On the same day on which the above debate took place Mr. Butler, President of the Board of Education, announced an important step in the development of meals for school children, stating that the Exchequer had approved an increase of 10% in the rate of grant on authorities' expenditure on meals. The Minister said he was placing at the disposal of local education authorities facilities for setting up cooking depots in all large centres of population. Mr. Butler also said that he aimed at increasing the proportion of children receiving milk in the "milk-in-schools" scheme from about 60%, where it now stood, to as near 100% as may be possible. As he pointed out, the efficacy of these measures depends upon the support given to them by local education authorities and teachers. There can be little doubt that if the feeding of the children of the country were put upon a proper nutritional basis much of the hospital accommodation that is at present the subject of debate will in the future become redundant. The introduction of compulsory midday meals for children in State schools, provided the parents contribute to the cost, can neither undermine their feelings of parental responsibility nor make them believe that the State is a kind of foster parent from whom all good things now and in the future must be expected to flow.

EXPERIMENTAL DIABETES

There are two ways of producing diabetes mellitus in animals: by pancreatectomy, which removes the secreting organ; and by injection of extracts of the anterior pituitary gland. It is nearly ten years ago since Evans and his co-workers observed that dogs treated for eight or nine months with injections of pituitary growth hormones developed persistent glycosuria. The experiments of Young, however, placed the matter on a firm experimental basis, and have led to much further work on the subject. The observation that a crude saline extract of beef anterior pituitary injected into dogs can cause permanent diabetes with all the associated clinical features is one to be placed on a par with the classical observations of Minkowski and von Mering. The aetiological implications of this research for human diabetes will be obvious to all, but in the meantime much work is required to identify the mechanism of the phenomenon and in particular the point of attack of the pituitary diabetogenic principle. That some substance from the pituitary actually antagonizes the action of insulin is suggested by the fact that hypophysectomized animals show much heightened sensitivity to insulin. But that the pituitary can secrete a substance that can interfere permanently with the control of sugar metabolism is a highly significant fact, for the implication is that the body carries within it an auto-lethal weapon and must, therefore, in its own defence constantly exert some controlling or neutralizing influence to combat it. In a sense all the internal secretions are at least dangerous weapons, and were it not for some equilibrating interactions between secretory activity and functional requirement the organism would always be in a state bordering on chaos. Hitherto, so far as we know, extracts have been made mainly from beef glands and injected into dogs, rats, and cats. In rats and cats the action is not so readily demonstrated as in dogs, but injection of anterior pituitary extracts combined with partial pancreatectomy, in itself insufficient to produce glycosuria, can also render these species permanently diabetic.

The permanent diabetes brought about in animals by a short treatment with extracts of the anterior pituitary has been named "pituitary diabetes," but this is not to suggest that the diabetes is maintained as a result of continued over-action of the pituitary. Indeed it is certain that this is not the case, for whereas the animal is resistant to insulin during the injections of the extract, it is no longer so after their cessation when the diabetes is established. It would seem, therefore, that permanent damage is somehow done and that this takes the form of atrophy of the pancreatic islets. Dohan, Fish, and Lukens,¹ using as diabetogenic agent a crude saline extract of frozen beef anterior pituitary lobes, have found that the time needed to induce diabetes in their dogs varies according to the doses given and to the nature of the dogs. Thus six dogs injected intraperitoneally with increasing doses became permanently diabetic in fourteen to forty-three days, and two dogs given small and fairly constant doses, in sixty-two to ninety-eight days; two dogs which failed to respond to large doses became permanently diabetic when partial pancreatectomy was followed by injection of a small amount of extract. After the establishment of the permanent diabetic phase, if no insulin were injected, 85% or more of the glucose available from all constituents of the diet could be found in the urine. Some slight evidence was obtained that insulin retarded the progress of the pituitary diabetes in two dogs, and that such dietary changes as fasting or fat feeding also had a similar temporary effect. Histological study of the pancreas of

¹ *Endocrinology*, 1941, 28, 341.

pituitary diabetic dogs showed that there was considerable atrophy of the islets of Langerhans, and such islets as remained consisted chiefly of the alpha cells. This atrophy is not accompanied by fibrosis: the atrophied islets seem to shrink and are smoothly replaced by acinar cells. There are variations in the severity of the clinical picture corresponding with the intensity of the effects on the pancreas, but if suitable conditions are chosen the full clinical picture is reproducible in all cases.

The extracts used contain other pituitary hormones, and some of their effects are observable in the injected animals. As to the nature of the diabetogenic substance and the actual amount of it injected there is no information. Whether the human pituitary can manufacture this substance is not known. But the glycosuria of the acromegalic may be due to the liberation of a similar substance. There are the observations by Davidoff and Cushing that of 100 cases of acromegaly twenty-five had glycosuria, and of these, twelve were cases of true diabetes. It is well known that if a pituitary tumour associated with acromegaly is removed the attendant diabetes may disappear, so that there was evidently no significant permanent lesion of the pancreas. As the glycosuria in acromegaly may be temporary in the developing stage of the disease or permanent after the disease is fully established, it would seem that it is all a question of the intensity of liberation of a diabetogenic substance in the early stages and the amount of islet tissue originally present in the attacked pancreas.

CONCENTRATED RED CELL SUSPENSIONS

Since the publication in this *Journal* in 1940 by MacQuaide and Mollison^{*} of their method of transfusing concentrated red cell suspensions this preparation has become increasingly popular. In our present issue members of the Merseyside Transfusion Service analyse the results obtained in seventy-seven transfusions of concentrated red cells. Blood in the bank is converted into plasma when seven days old. This is done by passing a sterile needle through the cap of the blood bottle and sucking off the supernatant plasma. After removal of the plasma the needle is passed down to the bottom of the remaining red cell layer, and the red cells are then in their turn sucked off into another bottle. A rather sticky layer of white cell debris and platelets is left behind. MacQuaide and Mollison originally suggested the addition of a small amount of 1.1% sodium chloride to the cells in order to reduce their viscosity. Williams and Davie found that in their experience such a solution caused undue haemolysis of the red cells, and since no difficulty was experienced on account of the suggested viscosity they add no diluting fluid to their cell suspensions. They emphasize the importance, however, of regulating the flow to not more than 100 c.cm. an hour in order to avoid the risk of cardiac embarrassment in anaemic patients who might be expected to have a damaged myocardium. Concentrated red cells, they suggest, should be used only for cases of chronic anaemia which require replacement of haemoglobin and red cells with minimal increase of circulating blood volume. They divide their cases into four groups: (1) post-haemorrhagic anaemias; (2) anaemias associated with severe infections; (3) anaemias of pregnancy and the puerperium; (4) dyshaemopoietic anaemias. Irrespective of the nature of the condition transfusion with one bottle of 500 c.cm. of concentrated red cell suspension raises the haemoglobin level between 10% and 12%. Exceptions to this rule occur. Low responses, Williams and Davie suggest, are usually due to a rapid exacerbation in the factors causing anaemia. Unexpectedly high results have in some instances been attributable to

operations which not only have removed the cause of the anaemia but may also have produced some degree of haemoconcentration. They point out that there is an unavoidable error in all the haemoglobin readings, since the estimations were made by different observers using different methods. The average figure does, however, agree reasonably well with that of other workers. The reaction rate is considerably higher. The gross reaction rate for the series was 19.5%. Grade III reactions (definite rigors associated with rise of temperature) representing 9.1% of the whole. This suggested that these figures are misleading, as at the time the observations were made Merseyside was subjected to severe bombing, and the usual provisions for pyrogen-free water were not available. Allowing for this disturbance of normal laboratory routine. Williams and Davie agree with MacQuaide and Mollison in believing that reactions with cell suspensions are less than with whole blood. They also describe a group of reactions which they considered allergic in origin: one, which is described in detail, proved fatal. At necropsy petechial haemorrhages were found in the myocardium. The possibility that such a death may have been due to transfusion of infected blood is not considered, and no mention is made of the result of cultures of the patient's or donor's blood. The authors suggest that all donors with a history of allergic manifestations should be excluded from regular panels.

LONDON VOLUNTARY HOSPITALS COMMITTEE

The Voluntary Hospitals Committee for London, elected in 1938, was an almost forgotten body during the early part of the war, for the main issues confronting the voluntary hospitals came within the scope of the War Emergency Committee of the British Hospitals Association, and there were few problems which did not also affect provincial hospitals and thus needed to be dealt with on a national basis. Later, however, questions have arisen affecting voluntary hospitals of London specifically, and the committee has become more active again. It has now issued a brief report for the eighteen months January, 1940, to July, 1941. It will be remembered that the committee represents three main groups of hospitals, each with an almost equal number of representatives—namely, general hospitals with undergraduate schools, general hospitals without schools, and special hospitals. The hope is expressed that the voluntary hospitals of London will take note of the committee's continued existence; by its constitution it is intended to be representative of the governing bodies and medical staffs, and if it is to achieve success, carry weight, and generally serve a useful purpose it must be sure of the support of its constituent hospitals. One piece of work carried out at its instance is the establishment by the King's Fund of a Contributory Schemes Committee for London, upon which the Voluntary Hospitals Committee itself, the King's Fund, the Hospital Saturday Fund, and the Hospital Saving Association are all represented, to deal with questions arising out of the work of contributory schemes and the relationship of such schemes to the hospitals. The chairman of the Voluntary Hospitals Committee is Mr. O. N. Chadwyck-Healey, the vice-chairman Dr. A. M. H. Gray, and the offices are at 10, Old Jewry, E.C.2.

The Hanbury Medal of the Pharmaceutical Society of Great Britain will be presented to Dr. Harold King of the National Institute for Medical Research, on Thursday, November 13, at 2.30 p.m., at 17, Bloomsbury Square. After the presentation Dr. King will give an address on chemistry and pharmacy, dealing with the mutual repercussions of the two subjects and having as its background the *British Pharmacopoeia* of 1932 and the Addenda.

EFFECTS OF EVACUATION AND OF AIR
RAIDS ON CITY CHILDREN

BY

W. MARY BURBURY, M.B., B.S., D.P.M.

Medical Director, Manchester City Child Guidance Clinic

An attempt is made in this article to assess the effects (a) of evacuation and (b) of air raids on the children attending the Manchester Child Guidance Clinic. So much has been written about the physical advantage to children of being out of big cities that it seems worth while to try in some way to assess and reduce to terms the psychological effects of war on them. Admittedly the numbers are small and represent a selected set of children in that they have been referred to a clinic of this nature, but in one group of figures these numbers are placed side by side with the total school population so that some comparison may be made. So far as the clinic is concerned the numbers represent all cases under treatment there in July, 1939, plus all those referred since that time up to March, 1941. From these figures only two groups have been excluded, the reason for exclusion being obvious: (1) cases coming from neutral and reception areas; (2) cases of proved mental defect.

TABLE I.—Relation of Clinic Cases to School Population

	Clinic Cases	Figures of Total School Population
Total number of cases	131	88,610
Total evacuated since September, 1939	88 (67%)	60,427 (68%)
Returned within 4 months	65 (50%)	65,301 (75%)
Further returned by end of 6 months	18 (15%)	12,065 (14%)
Still evacuated	5 (4%)	
Evacuated after raiding began	20	Further figures not available owing to continuous re-evacuation
Returned within 3 months	3	
Still evacuated	17	

Table I is designed to show the relation of the clinic cases to the general population, and is self-explanatory, except that it should perhaps be stated why the periods of four months and six months have been chosen. The four-months group comprises the children who either failed in evacuation from the beginning or who at any rate were unable to weather the Christmas holiday period. The six-months period is intended to be rather an elastic one covering those children who returned between Christmas and Easter or with their schools at Easter. A considerable number definitely came back for this latter reason, or because they obtained places in secondary schools which themselves had returned. It will be noticed that while the figure for the original evacuation of clinic cases is closely parallel to the percentage of the total school population which evacuated, the children who returned show a considerable discrepancy. It is difficult to explain this or to be sure whether the fact that we were able to pay regular visits to the parents contributed anything towards their stability in this matter.

Table II is an analysis of the reasons for which these children returned and needs more explanation. Under the

heading "Parents' Request" are the cases in which the parents wished to take the child home. The reasons for this change of attitude are important. There was first the question of billeting costs. Only two of the parents complained of this, and in one case the complaint was quite unrelated to reality, and occurred in a family the father of which was in a regular and stable job and before any question of active contribution by parents had been raised. The commonest reason was just that the parents wanted the children home. Some of these cases are perhaps worth quoting, since they show that the parents themselves were maladjusted people.

Case 1.—Girl aged 11. I.Q. 96. Youngest of a family by twelve years; unwanted by mother, who felt very guilty about her feelings. Evacuated in September. Brought home in November. The mother reports: "I was afraid something might happen to her. I thought she wasn't happy. They said she was. I think she was afraid of hurting their feelings."

Case 2.—Boy aged 17. I.Q. 122. Referred for stammer. Father committed suicide, and the boy had found him dead. Youngest of the family and the only one living at home with the mother, the others being married. In a secondary school and doing well. Brought home because the mother was lonely.

Case 3.—Boy aged 12. I.Q. 87. Referred for truancy and pilfering. A difficult, very anxious boy whose mother was in a state of chronic ill-health, and who was extremely antagonistic to all his home surroundings; was taken home suddenly by his father because the foster-parents complained that he was difficult to manage.

Under the heading "Child's Request" we have included those cases in which the child requested and was allowed to come home. Nearly all these cases are reported as "home-sickness"; but in a few the child complained of being lonely when alone in a billet or objected to the billet; one disliked having to be in bed by 6 p.m. Two were specifically anxious about the parents at home.

Case 4.—Boy aged 11. I.Q. 156. Ran away from billet. A stammerer. Ambitious over-earnest parents who are afraid he will not get on, as he is too interested in cricket. He took another boy with him, and they started to walk back home, a distance of some fifty miles, and when this proved impossible went to get advice from the police.

Case 5.—Girl aged 13. I.Q. 111. Referred for truancy. Evacuated at outbreak of war. Returned because she was unhappy and lonely. Is an only child, brought up at first by grandmother because mother wanted to continue going to work; feels neglected in her home and anxiously tries to behave in a grown-up way. Over-developed physically, and looks and behaves like 16. Makes fantasies of having brothers in the Services and of having children; she always has twins, so that they will not be lonely.

The third and biggest group is that in which the request came from the billet, and in it are detailed the various symptoms of which complaint was made; the simple heading "Personal Difficulty in the Billet" is self-explanatory. Perhaps the most interesting feature of this group is that in all the cases under the heading "Truancy" the symptom is said not to have occurred before the war started. This is borne out by an investigation which we recently conducted into cases of truancy reported to this clinic. We found, starting from September, 1937, when the clinic was reorganized under the local authority, that between

TABLE II.—Cases Evacuated in September, 1939; showing Reasons for Return and Apparent Effect of Evacuation

Reason for Return	Age Group			I. Q.			Apparent Effect of Evacuation			Unchanged by Evacuation
	5-8	8-12	Over 12	B.	N.	S.	Better	Worse	Symptom attributed to Evacuation	
Parents' request	5	8	1	3	6	5	2	5	—	6
Child's request	..	7	14	5	10	8	2	4	6	5
Billet's request:										
Enuresis	1	1	2	—	1	3	—	3	—	1
Pilfering	..	4	1	1	3	1	—	—	3	1
Truancy	..	4	3	3	2	2	1	3	2	3
Unmanageable	..	5	4	1	5	3	—	—	1	4
Illness	..	2	1	1	3	—	—	1	1	1
Personal difficulty in billet	..	3	3	1	4	4	1	1	2	4
Other reasons	2	2	6	1	—	—	—	—	—	—
Total	6 (8%)	17 (24%)	19 (28%)	31 (43%)

September, 1937, and September, 1939, 48%, and between September, 1939, and March, 1941, 52% of the total were referred for truancy, though the clinic was closed for two months and was working short time for another two. Of these truants two entirely ceased when they returned home and one after a short period of treatment. Of the pilferers whose symptom was apparently produced by evacuation, one has since died, one has now adjusted himself, and one has continued to steal. Of the group reported unmanageable, one came from a very disturbed home, where the father and mother were in constant disagreement, and the father violent and gaining his ends by violence. This boy's violence started when evacuated, but continued in his own home and, indeed, in any situation in which he was frustrated; a second was returned after three days as incorrigible: he had twitches and temper tantrums, but reacted well to treatment in a group and is now adjusted at home. He shows no anxiety in raids. The cases of enuresis form another interesting feature. Three out of four of these were worse as the result of evacuation, two of them advancing to faecal incontinence during evacuation. It is perhaps noteworthy that all these three are children of very superior intelligence, and that two of them have been very greatly improved with a short period of treatment. The one case of which we have no record we have been unable to trace since the original inquiry as to which of our patients were evacuated.

The results of this investigation go to show that emotional difficulties were either started or made worse in 52% of the cases examined and that in only 8% was the condition improved. One of this last group had been under treatment at the clinic for two years. She had originally been sent for refusing to go to school, or indeed to leave her mother at all, and we had the greatest difficulty in maintaining contact with her. During the period of treatment she gradually freed herself of her mother, at first consenting to being seen alone, then to making the journey alone, then to taking a clerical course in a commercial school, three of which she tried before finally settling down in one. She finally evacuated with this school and returned because she had completed her course. She was originally referred at the age of 13, and had on test then an I.Q. of 106; she was retested by the same psychologist after two years of treatment and had then an I.Q. of 126. She is now in a good job, which she has held eighteen months. While it is in a sense incorrect to say that evacuation helped this girl, since she was so far improved before it, it is nevertheless true that it helped finally to confirm her confidence and independence, and she proved by week-ends at home her ability to go and come as she wished.

Table III refers to the immediate effect of air raids on children examined. We feel that the word "immediate" should be stressed, since we are not yet in a position to assume that we know what the final effect of living in constant risk of this sort of warfare is going to be on either the adult or the child population. It would perhaps be as well first to dismiss the last group, unfortunately a large one, in which we have no report of the child's reaction to raiding. We have therefore written them off as "no change," with the exception of five who are known to have responded badly to evacuation. The reason for this lack of reports is certainly partly that a number of these children

have been re-evacuated, especially since a bad raid at Christmas, 1940, and the parents have probably for this reason failed to answer letters referring to what they doubtless consider a past problem; partly that some of the cases are those discharged from the clinic a long time before, the parents again considering this a raking-up of old difficulties. It was impossible to visit personally so large a number of cases, so that inevitably the work was done by questionnaire. Finally, there undoubtedly exists in some parents' minds the fear that to admit that the child is anxious may lead to his compulsory evacuation.

In the other two groups there are one or two outstanding cases. First there is the single case reported as improved in spite of anxiety in raids. The symptom in this case was truancy from school. The boy was an adolescent in a central school, of superior intelligence, very over-protected by his mother. He broke down in evacuation when he was separated from this protection and anxiety on his behalf, and continued to be difficult on return, trading on his power over his mother, who went so far as to excuse him from attending the clinic when he found it difficult. He has now become an air-raid messenger, and this adult position of responsibility appears to have helped him to a stability in other directions also. It is true that he has perhaps not been in real danger, since he lives on the outskirts of the city, where bombing is slight; but he has nevertheless achieved an adult position, which his mother would never allow him, and has responded to it by giving up his truancy. The statement that he is anxious comes from the mother, who herself is very disturbed by raids.

The next interesting feature is the group of cases in which the symptom was attributed to raids. One of these was sleep-walking in a girl, accompanied by anxiety dreams of "Hitler stabbing her"; the second was general "nervousness"; three were cases of truancy, the second of these being especially striking:

Case 6.—A boy aged 11. I.Q. 82. Referred for truancy from school. He has a cataract in one eye and is afraid of the other boys. Cannot stand up for himself. This boy, after being bombed out of one of the most devastated areas, denied all anxiety in the raid, saying: "The whole of the back of the house fell down and we were sitting on the cellar stairs, and mother was afraid, but I wasn't"; and then described a dream in which he was "shooting at Germans coming down in parachutes, but, of course, I wasn't afraid, but mother is afraid of invasion."

Of those whose symptoms were aggravated by raiding three are enuretics, and the aggravation in two of these bears a definite relation to nights when there are raids. One of these two is a child of 8 with a self-assured manner and a swaggering walk who constantly plays with toys representing the street of a town, with everything huddled close together; always there is a protective fire-engine and sandbags, but the play includes no aeroplane. Two are stammerers: in one of these the stammer is slight except when he is brought to talk on either evacuation or air raids, when it becomes noticeably worse. Two were reported unmanageable and to be pilferers, and one as over-aggressive and quarrelsome. One child aged 8, whose parents insisted he was quite unmoved, produced the following gruesome fantasy, none of which is fact, as there was not even an alert. "Last night I was coming out

TABLE III.—Immediate Effect of Air Raids (Total Number known to have experienced Raids, 114)

Reaction to Raids	Age Group			I.Q.			Effect on Symptom				Symptom attributed to Evacuation	Type of District		
	5-8	8-12	Over 12	B.	N.	S.	Improved	Worse	No Change	Symptom attributed to Raids		Heavily Bombed	Moderately Bombed	Lightly Bombed
Anxious ..	4	14	9	10	11	6	1	14	6	5	5, in 4 of which raids also made matters worse	6	6	15
No apparent anxiety ..	7	26	20	8	25	17	—	4	38	1		5	14	34
No report ..	6	16	12	6	19	9	—	—	29	—	10	5	15	11
Total	1 (1%)	18 (15%)	73 (62%)	6 (5%)	20 (17%)			

of the pictures when the sirens went and a little boy ran across the street, and they dropped a bomb and it went through his back and he was killed, and I went and told his mother and she screamed."

In the second group one case stands out as noteworthy. This boy was referred as a pilferer and as stopping out late at night and being unmanageable. He came from an extremely unhappy home where quarrelling was incessant. Both parents were almost blind; the father was desperately ill and very irritable and difficult in the home, which was completely comfortless and in a heavily bombed area. His father died on the night of an air raid, and he showed no feeling about either one event or the other. One feels that this lad could permit himself to feel nothing lest life should become intolerable. Another was reported to be unaffected, yet will only sleep downstairs. Another, an adopted child, was said to "enjoy" raids and to stay out at night. As this left her adoptive mother alone in the house one wonders whether the mother's conclusion was really the correct one or whether the going out might not have been a deliberate act of aggression against her, as she is undoubtedly afraid.

Conclusion

It is striking that there seems to be little relation between heavily bombed areas and anxiety about raids. This point is strengthened by the fact that in another group of clinics situated in reception areas we have received from parents more complaints of children being anxious and disturbed by talk of raiding or sound of sirens, and that of these cases only two are evacuated from heavily raided areas; the rest have experienced little more than the sound of sirens or distant guns.

The general conclusion to be drawn from these investigations would seem to be that, whatever the ultimate outcome, the immediate effect of evacuation, which is separation from parents and a known and accepted environment, is worse than the immediate effect of raiding—that the fantasy, waking or dream, of the raid is provocative of greater anxiety than the reality.

I wish to thank the Director of Education for Manchester for kind permission to publish these cases, and the staff of the Manchester Child Guidance Clinic for their help in collecting the material.

WARTIME PRESCRIBING

SCOPE OF NATIONAL WAR FORMULARY

Elsewhere in this issue the attention of practitioners is drawn to the *National War Formulary* (H.M. Stationery Office, 6d. net.), compiled by a committee appointed by the Minister of Health. Below we give some account of its scope and contents. From December 1 next this *Formulary* will replace the present *National Formulary* for national health insurance purposes, and on and after that date no preparation should be prescribed by title only unless its formula is contained in the *N.W.F.*, the *British Pharmacopoeia*, or the *British Pharmaceutical Codex*.

Under the heading of "Wartime Prescribing" it offers some remarks on general limitations. Agar, for example, should be reserved for bacteriological uses; the use of cinchona as a bitter is discouraged; quinine should be reserved for the treatment of malaria; digitalis is best administered as 1/2 and 1 grain tablets of powdered digitalis; and ergot, the liquid extract of which is not an economical preparation, is also best administered in tablet form. Vitaminized oil B.P. has the same vitamin content as a high-grade cod-liver oil, and is a satisfactory alternative in most cases. Economy in alcohol is essential, and alternatives to alcohol are suggested for preserving surgical instruments from rust, and to surgical and industrial methylated spirit for the prevention of bed-sores. A circular on economy in the use of alcohol in surgery was recently issued by the War Wounds Committee of the Medical Research Council. Liquid paraffin also must be prescribed with due regard to economy; where oral administration is considered necessary economy can be effected by using a 25% emulsion, but this, too, should be used sparingly.

Liver extracts are controlled under a Defence Regulation; they are not to be administered save to persons suffering from pernicious anaemia or other megalocytic anaemias, nor given otherwise than by injection. Malt extract and preparations containing it should be prescribed only for children and tuberculous patients. Phosphorus is wanted for munitions. Phosphoric acid has been replaced by hydrochloric acid; hypophosphites and glycerophosphates have been excluded, and sodium acid phosphate remains only for use in association with hexamine. Potassium compounds should be prescribed only where the corresponding sodium compounds are not satisfactory, but potassium acetate and potassium chlorate have been retained as the sodium salts are not satisfactory alternatives.

Prescribers are advised against the ordering of confections and lozenges, which require sugar. Dextrose and glucose are rarely necessary except for intravenous and rectal administration. Sulphanilamide, sulphapyridine, and sulphathiazole in tablet form are included in the *Formulary*, but there is a note that the first of these is the most generally useful drug in the group, and should be prescribed unless there are specific indications for either of the others. A list of more than a dozen other drugs and their preparations which should be prescribed with particular regard to economy is given; these include salicylic acid and its salts, mercury and its compounds, hyoscine, and atropine. It is enjoined that the use of distilled water should be restricted to preparations for application to the eye and preparations in which, in the opinion of the dispensing pharmacist, the use of ordinary potable water would result in an undesirable alteration to the medicament.

Proprietary preparations, particularly those of foreign origin, should be avoided if possible. Many of them, in any case, are unobtainable, and their prescription would lead to inconvenience and delay. A list is given of proprietary drugs with corresponding non-proprietary equivalents, and prescribers are urged if possible to use the B.P. preparation.

Replacements and Limitations

Briefly to glance at some of the formulae, the first list is of six preparations for ear-drops. These are the same as in the *N.H.I. Formulary* save for some reduction of glycerin and rounding off of percentages. Five forms of capsule are indicated, but it is stressed that tablets and pills are generally preferable. Certain capsules formerly described, such as those of ergot, sandalwood oil, and preparations of iron, are omitted. On the other hand, capsules of concentrated solutions of vitamins A and D and of halibut-liver oil are added. The linseed poultice is discouraged; the only entry under "Poultices" is the kaolin poultice B.P. Among mouth washes the principal changes are the substitution of sodium for potassium and a new formula to replace glycerin of thymol.

Four flavouring and sweetening emulsions—aniseed, aniseed with peppermint, chloroform, and peppermint alone—have been introduced for mixtures in place of alcoholic preparations. Enemas are a new group as compared with the old *Formulary*; they include enemas of ox bile, of soft soap, and of oil of turpentine. The glycerins number two. A solution containing 25% of glycerin and 10% of sodium chloride has been introduced for intra-uterine use in place of pure glycerin. A glycerin of proflavine, which is evidently considered an improvement on acriflavine, is also included. The injections are mostly B.P. injections, but a new one, injection of papaveretum (2%), an antispasmodic preparation (dose, 5 to 10 minims), has been introduced. As a vaginal injection zinc sulphocarbolate is replaced by zinc sulphate. A good general linctus, with syrup as the basis, has been provided; in spite of economy in the use of sugar the need for one good sweet preparation was felt.

Linctus Simplex (Linct. Simp.)

Dilute sulphuric acid	5 minims
Emulsion of anise N.W.F.	24 "
Emulsion of chloroform B.P.C.	5 "
Solution of Bordeaux B.P.C.	1 minim
Syrup	to 60 minims

Liniments have been so framed as to save alcohol and to exclude the drugs mentioned for exclusion in the War Medical Handbook of the M.R.C. It is mentioned that strict economy should be observed in prescribing liniment of soap B.P. because it contains so much alcohol.

The formula of liquor antisepticus has been changed to suit wartime conditions. Chlorine antiseptics have also been excluded. Eusol is not recommended, as being unstable; it is hauled. Dakin's solution or a new 2% solution of chlorhexidine is preferred. A borax and formaldehyde solution is given for use in place of alcohol for preserving instruments in a

condition and free from rust. This is one of a number of possible formulae for a solution to replace spirit. It is possible that it might be improved by the omission of formaldehyde, to which some surgeons object, and the substitution of chlorocresol for phenol. A new lotion containing 25% of sodium sulphate, approximately saturated at ordinary temperatures, is included for the hypertonic treatment of war wounds and similar conditions. Lotion flavinae, formerly an undefined term, is now specified as a 0.1% solution of proflavine sulphate in normal saline solution.

A Wide Choice of Mixtures

The mixtures—a long list—have in many cases new names, but cross-references to the old mixtures are given. Gentian is replaced by quassia, magnesium sulphate by sodium sulphate, alcohol is reduced in quantity everywhere, glycerin is excluded, phosphoric acid replaced by hydrochloric acid, extract of liquorice as a sweetening agent removed or reduced in quantity. For example:

Mistura Quassiae Acida (Mist. Quass. Acid.)

Dilute hydrochloric acid	10 minims
Infusion of quassia	120 "
Chloroform water	to ½ fl. oz.

Dose: ½ fl. oz. three times a day in water.

Bismuth mixtures are entirely discouraged, a list of six alternatives being given, among them new mixtures containing magnesium trisilicate and kaolin, thus:

Mistura Magnesii Trisilicatis Composita (Mist. Mag. Trisil. Co.)

Magnesium trisilicate	10 grains
Light magnesium carbonate	10 "
Sodium bicarbonate	10 "
Peppermint water	to ½ fl. oz.

Dose: ½ fl. oz. three times a day in water.

Mistura kaolini is similar, 15 grains of kaolin replacing the magnesium trisilicate.

A new formula for mistura diuretica is:

Mistura Potassii Acetatis (Mist. Pot. Acet.)

Potassium acetate	30 grains
Decoction of broom B.P.C.	to ½ fl. oz.

Dose: ½ fl. oz. three times a day in water.

Cough mixtures are the subject of a special paragraph. A list of nine is given, and there is a note: "If mistura tussis is prescribed without qualification mistura ammoniae et ipecacuanhae composita will be supplied":

Mistura Ammoniae et Ipecacuanhae Composita (Mist. Ammon. et Ipecac. Co.)

Synonym: *Mistura Expectorans, Mistura Expectorans Nigra, Mistura Tussis*

Ammonium carbonate	3 grains
*Liquid extract of ipecacuanha	½ minim
†Concentrated camphorated solution of opium N.W.F.	2 minims
Solution of burnt sugar B.P.C.	7½ "
Water	to ½ fl. oz.

Dose: ½ fl. oz. three times a day in water.

* Equivalent to 10 minims tincture of ipecacuanha.

† Equivalent to 16 minims camphorated tincture of opium.

Sprays, Pastes, and Powders

The list of nebulae includes a new aqueous ephedrine spray (1% in a 0.5% saline solution). Among the pastes is the following new formula:

Pasta Picis Carbonis (Past. Pic. Carbon.)

Commercial coal tar	14 grains	3% approx.
Zinc oxide	120 "	25% "
Starch	120 "	25% "
Yellow soft paraffin	to 450 "	100% "

In wartime strict economy is essential in prescribing this paste. The use of magnesium sulphate paste is not favoured, and the hypertonic lotion of sodium sulphate is recommended as an efficient alternative. The pigments include the following formula for pigmentum triplex, suggested in treatment of burns:

Pigmentum Triplex (Pig. Triplex)

Crystal violet	1 grain	0.25% approx.
Brilliant green	1 "	0.25% "
Proflavine sulphate	½ "	0.1% "
Distilled water	to 1 fl. oz.	100% "

The powders include flavoured preparations of barium sulphate and iodophthalain for diagnostic purposes:

Pulvis Iodophthalaini Compositus (Pulv. Iodophthal. Co.)

Iodophthalain	60 grains
Citric acid	24 "
Lactose	80 "
Sucrose	to 240 "

Dose: 240 grains in a tumblerful of water, stirred until mixture is white.

For internal use, to replace compound bismuth powders, powders containing kaolin and magnesium trisilicate are prescribed, thus:

Pulvis Magnesii Trisilicatis Compositus (Pulv. Mag. Trisil. Co.)

Magnesium trisilicate	240 grains
Sodium bicarbonate	240 "
Heavy magnesium carbonate	240 "
Chalk	240 "

Dose: Half a level teaspoonful in a little water.

Note: The titles "alkaline powder" and "pulvis alkalinus compositus" should not be used to describe this or any other preparation.

Pulvis Kaolini Compositus (Pulv. Kaolin. Co.)

Sodium bicarbonate	160 grains
Heavy magnesium carbonate	320 "
Kaolin	to 960 "

Dose: One level teaspoonful in water or milk.

There is a long list of tablets, and the new ones include ascorbic acid, nicotinic acid, aneurin hydrochloride, sulphaniilamide, sulphapyridine, sulphathiazole, laxative compound (cascara compound), digoxin, and stramonium. Sulphathiazole is, however, very scarce at the present time, and, although the tablets are included in the N.W.F., practitioners are requested, in order to avoid delays and difficulties, to refrain from prescribing them for the present.

The Children's Section includes a zinc cream, three malt extract preparations, a simple linctus, and a number of mixtures, several of which are the same as in the General Section but in smaller doses. In the Children's Section it is considered that a reasonable use of syrup may be made.

It will be seen from this outline that the compilers have held the balance between what is necessary in prescribing and the requirements for the war effort. It is to be hoped that practitioners will second their endeavours.

DRUGS EXEMPT FROM PURCHASE TAX

It will be remembered that in the early announcements on the application of the Purchase Tax to drugs and medicinal preparations (*Journal*, February 1, 1941, p. 163) total exemption from tax was allowed in the case of "essential drugs of an exceptionally costly character." This, as we pointed out, was a clumsy definition, and the first list of the drugs covered was obviously incomplete. The Commissioners of Customs and Excise have now issued in Notice No. 78B a schedule of the classes of drugs which are exempt from the tax. These are as follows (Group 5 is not included, as it refers to substances to be used solely for veterinary purposes):

Group 1.—Exempt only when sold without any added substances: Bromethol; chloroform (anaesthetic); cyclopropane; ether (anaesthetic); ethyl chloride; nitrous oxide; oxygen.

Group 2.—Exempt whether sold as such or prepared with an excipient, vehicle, base, or preservative (mixtures of these substances and mixtures of one or more of them with any other substance not being an excipient, vehicle, base, or preservative, are chargeable): Liver extracts and active principles of liver. Insulin, and compounds whereof the sole constituents are insulin, protamine, and zinc. Preparations of the parathyroid glands. Pituitary (posterior lobe) extract as defined by paragraph 1 of the Fifth Schedule to the Therapeutic Substances Regulations, 1931, made under the Therapeutic Substances Act, 1925, and other preparations of the posterior lobe of the pituitary gland. Thyroxine and preparations of the thyroid gland. Oestrone, oestriol, oestradiol, esters of any of those substances, stilboestrol, and hexoestrol. Extracts of the cortex of the suprarenal glands: corticosterone, desoxycorticosterone, and esters of corticosterone and desoxycorticosterone. Extracts of the corpus luteum: progesterone, and the substance commonly known as pregnenolone or anhydrohydroxyprogesterone. Testosterone and its esters. Chorionic gonadotrophin (human). Desiccated stomach. The dimethylcarbamate ester of 3-hydroxyphenyl-trimethylammonium-methylsulphate.

Group 3.—The following may be mixed with one another and with an excipient, vehicle, base, or preservative, and still be exempt, but

the presence of any other substance makes the mixture chargeable: Adrenaline and its salts; amylocaine hydrochloride; arspenamine, derivatives of arspenamine, and salts of such derivatives; cocaine and its salts; ergometrine and its salts; hexobarbitone and hexobarbitone soluble; morphine and its salts; papaveretum; para-aminobenzenesulphonamide and its salts, derivatives of para-aminobenzenesulphonamide having any of the hydrogen atoms of the para-amino group or of the sulphonamide group substituted by another radical, and salts of such derivatives; procaine and its salts; the sodium salt of 5-ethyl-5-(α -methylbutyl)-thio-barbituric acid.

Group 4.—Sera, vaccines, toxins, antitoxins, and antigens which are subject to control and licensing under the Therapeutic Substances Act, 1925, are exempt when prepared for use by injection or by application to the scarified skin; mixtures so prepared are also exempt.

Group 6.—Phenthiazine or thiodiphenylamine is exempt when sold as such.

It is also announced that forceps and tweezers exceeding 3 inches in length or shaped away from the straight, scalpels, lancets, and other chiropody knives with metal handles are exempt from tax.

THE BRITISH HOSPITALS ASSOCIATION

The address of Sir Bernard Docker, chairman of the British Hospitals Association, at the recent annual general meeting of that body, touched on several matters of present and future interest. The first was nurses' salaries. He said that the Minister of Health had announced increases of salary, not only for the Civil Nursing Reserve but for hospital nurses generally. The association had endeavoured to secure financial assistance from the Ministry to enable hospitals to meet the cost of raising nurses' salaries. The Minister's first suggestion was to give certain assistance to voluntary hospitals through local authorities in a manner which was not acceptable, but the association had now been appointed by the Government to distribute grants for the purpose of meeting the cost of the increases. This meant that the association had been recognized as the central and representative body. The association had been considering its policy with regard to co-ordination of hospital services. The statement of policy was now in draft and would be issued shortly.

With regard to the position of hospital staffs called up for various forms of war service, strong representations had been made to the Government on the need for reservation. It was clear that, unless some arrangements of a better nature than those obtaining at present were made, hospitals might be compelled to stop their work, not for want of medical or nursing skill but for want of other staff.

Sir Bernard Docker went on to refer to the reply given in the House of Commons on October 9 by the Minister of Health to a question by Sir Francis Fremantle on post-war hospital policy and organization. He saw nothing in Mr. Ernest Brown's statement that was not fair, friendly, and helpful. The association was in agreement with the object of making the hospital services readily available to every person in need of them. It was evident that the Government intended to maintain the principle by which patients were called upon to make reasonable payment towards cost either through contributory schemes or directly.

Finally he touched upon the scheme recently propounded—and indeed created—by Lord Nuffield, with the object of assisting the formation of mutual insurance to assist the middle and professional classes to meet the cost of specialized or surgical treatment in hospital pay-beds or nursing homes. It will be recalled that Lord Nuffield has established a Provident Guarantee Fund of £150,000 with this end in view (*British Medical Journal*, October 25, p. 584). Sir Bernard Docker said that his association could and should subscribe to this policy. He also welcomed a Government announcement that increased educational grants for teaching hospitals were contemplated. He ended with a tribute to the Minister of Health for the open-minded way in which he had consulted the association on various matters. The Minister had said that it was intended to lay on local authorities the duty of securing close co-operation with voluntary hospitals. Sir Bernard Docker would have welcomed an indication that he was prepared to offer voluntary hospitals a share in statutory responsibility.

Reports of Societies

WATER DEFICIENCY

At a meeting of the Section of Medicine of the Royal Academy of Medicine in Ireland, when Dr. A. R. PARSONS presided, Dr. R. H. MICKS read a paper on water deficiency.

Dr. Micks said he intended to discuss the problems of dehydration without reference to the dehydration of surgical shock or the dehydration caused by extensive burns. So much knowledge of these two subjects was at the moment being acquired in other countries that it was too early to attempt to lay down a systematic teaching on the subject. The phenomena of water deficiency might be divided into three stages: the first, those of the falling water reserve, symptomless except for the loss of about one-twentieth of the body weight; second, those of dehydration without circulatory collapse, the symptoms of which were a dry tongue, loss of elasticity of the skin, haemoconcentration, and the beginning of impairment of renal function; third, dehydration plus circulatory collapse. The recognition of the first stage was important, as the proper treatment of dehydration was to anticipate its onset, as could easily be done by careful measurement of the water balance, or, in the infant, frequent weighing. When dehydration was due to excessive loss of body fluids the administration of sodium chloride was just as important as water. In dehydration plus circulatory collapse the intravenous route should be used, and at times hypertonic saline was required. In general the solution administered should be normal saline, but there was evidence that for rapid rectal absorption 0.18% saline was better. Glucose solutions were not necessary except when parenteral feeding had to be maintained for a long time, and sometimes in diabetic coma. There was little reason to think that either special alkalizing fluids or fluids containing calcium or potassium salts were useful, except, possibly, in certain rare cases. Dr. Micks pointed out that there was a danger of over-emphasizing the intravenous route, which was only required in emergencies. In many cases fluid could be administered orally or by nasal tube. Rectal drip, too, was satisfactory in many cases, and enough fluid could be given that way to maintain life and compensate for a considerable abnormal loss. Subcutaneous administration of large volumes of fluid was little practised now, while the intraperitoneal route he considered to be usually unsatisfactory, as little fluid could be administered.

Prof. W. R. FEARON pointed out that water deficiency was usually a question of salt deficiency and salt balance. Once the cell membrane was complete the ions did not tend to escape readily from the cell. There was no mechanism equivalent to that of thirst to indicate when there was too much water in the body. If the osmotic pressure of the urine were known the osmotic curve from hour to hour could be drawn, thus indicating the state of water balance at any time. The treatment of dehydration was physiologically the administration of saline. There was no doubt that far more harm was likely to be done by giving too little water than by giving too much. Prof. W. J. E. JESSOP considered that water restriction in cases being treated by sulphonamides was dangerous on account of the formation of drug crystals in the kidney. He had found such crystals, which had proved to be sulphapyridine. They were deposited on account of the insufficient fluid intake of the patients.

The President (Mr. SETON PRINGLE) said that surgeons had recognized earlier than physicians the possibility of severe and perhaps fatal dehydration. He had been a pupil of Arbuthnot Lane, who in every major operation had inserted a needle under each breast and had given two or three pints of saline. This, of course, was not always applicable, but it was a very great help in the first and second stages of dehydration; it was useless in the third stage. He had found that saline without glucose gave a most satisfactory result. Rectal drip had been the routine method for many years, but in many patients it had proved uncomfortable and inconvenient. If serious dehydration was feared this method was tedious and not really satisfactory. Instead of this drip method a reservoir of saline was now used, which was connected with the rectum through a tube.

wide tube; the saline was only taken up from the bag as it was needed, and thus the rectum never became distended or uncomfortable. Prof. T. W. T. DILLON pointed out that one of the most important things was to have some easy test which would show when enough water had been given. The obvious place to look for such a test was in the urine. If the specific gravity of the urine was taken it would be seen that water repletion coincided with a sharp fall in specific gravity. Dr. R. E. STEEN said early treatment of dehydration was important in cases of gastro-enteritis. While he had had no experience of saline by the intramuscular route, he thought it was possible to give an equal amount more satisfactorily intravenously. There were certainly definite indications for the intravenous drip method in young children.

Mr. J. C. FLOOD thought it wise to emphasize that too much water might be taken. Up to about two years ago there had been a tendency to give water under every condition of surgical collapse. One had to distinguish between dehydration due to water going out of the body and that due to water coming out of the blood channels. There was considerable chance of the patient being over-dosed if he was suffering from shock associated with a water shift out of the blood vessels into the tissues. When a patient was receiving post-operative transfusions and salines a record should be kept of the total fluid intake and the total fluid excretion every day. Dr. A. SPAIN did not consider that the intravenous route was suitable in an emergency away from a hospital. In such cases the subcutaneous route was very efficient; it was astonishing the rapidity with which a patient would absorb fluid if one pint was put under each breast. This could be done without causing the patient any inconvenience.

Correspondence

Post-war Medicine

SIR,—Much has been written recently on the future of the medical services of this country, and it is perhaps of interest to analyse the factors which have created the present feeling of instability.

1. It is more than probable that the post-war Government will be either socialistic or semi-communistic. The Conservative Party will almost certainly be defeated, for the Labour Party will hold them responsible, rightly or wrongly, for pre-war diplomacy and inadequate preparation for war. The Socialists are already pledged to State medicine and will carry out this policy at the first opportunity.

2. Voluntary hospitals and organizations have previously depended upon charity. It is difficult for anyone to believe that the finances of the country will be able to bear the strain of distributing charity to voluntary hospitals and organizations. Moreover, it is unlikely that bequests to State-aided institutions will be made with any frequency. This implies that voluntary hospitals and organizations must become in time State-aided and perhaps State-controlled.

3. In modern civilization the medical services are far too elaborate and expensive to be dependent upon charity alone. It is argued by some that no sick person should be dependent upon charity for hospital treatment, and that the care of the sick should be the business of the State, just as it is the affair of the Government to educate the children of the working classes.

4. The moment is ripe for planning and reorganization. Surely the first step is to plan a medical Utopia and to let all efforts be directed towards establishing this ideal state of affairs. A medical Utopia cannot be obtained immediately, and obviously many years must elapse before it can be established in running order; yet if the ideal is before us every alteration in the medical services should be directed toward this goal.

5. Correspondence in the medical journals has shown that there is a haunting fear among medical men that they may be smothered by red tape and faulty administration from Govern-

ment bureaucracy. It is most likely, however, that drastic changes will be made in Government administration as a result of the very severe criticisms which have been made during the present war. Furthermore, few people can complain of the efficiency with which the Treasury extracts income tax from us all. Medical men as a whole love their independence, and one of the greatest attractions of the profession is that a man, if he chooses to do so, may carry on his professional work with few restrictions and little interference from higher authorities. Many medical men therefore look with dismay towards the prospect of their professional work being controlled by the State.

The Government has now committed itself to reconstruction and replanning of the nation's medical services. It seems to me that such reconstruction should be planned by the best intellects of our profession. It is essential that the medical profession itself should play a very important part in the reconstruction. Perhaps the best solution would be for a Royal Commission to investigate the problem. The Commission should contain men nominated by the General Medical Council, the British Medical Association, the Medical Research Council, and the Ministry of Health. The Treasury and the Ministry of Public Works and Buildings would have to be represented as well. In my view the members of the committee should be young men under the age of 40. We should remember what was achieved by the young men at Johns Hopkins, and history shows that a man's best original work is usually done before the age of 35. Originality and thoughts of the future are much more important in the work of reconstruction than remembrances of past glories.

In my view it would be a great mistake for the work of reconstruction and the formation of policy to be in the hands of Government Departments. The findings of a Royal Commission would be above the level of Government Departments, and this is perhaps the fundamental consideration.—I am, etc.

Bradford-on-Avon, Oct. 25.

WILFRED SHAW.

The Optimum Size of an Organization

SIR,—Recent discussions open a great problem which must be faced. The optimum size of any organization is a modern problem which is rapidly gaining in importance and receiving attention. It has arisen in my mind largely from the growth of the Victorian Bush Nursing Association. There are built, and organizing, sixty-two hospitals, none of which provides more than thirty beds, mostly less, with a total of more than 700 beds. They are one-storied. They provide bedrooms with one or two beds, and in the later types no wards. They are staffed by doubly and trebly certificated nurses, not by trainees. They receive no Government aid, except passes on the railways for the nurses, but they can, and do in some cases, receive municipal aid. The charges to those who pay 30s. a year subscription for themselves and their children up to the age of 16 are, I think, the lowest in the world for superb accommodation, being about £2 12s. a week—less before the war. They are decentralized and managed locally, subject to the general rules of the association.

People naturally think that if this large number of operating rooms, bathrooms, and nurses' quarters (which are excellent) could be placed in one building the cost of building and administration would be much less. As a matter of fact it would be multiples of their cost. They cost up to £400 a bed, and until the war usually less. The large city hospitals have cost from £1,600 to £2,000 per bed. The personal attention in the small hospital is a factor to which the country people are keenly alive. They have a maternal death rate of 2 per 1,000, whereas the State has a rate of 4.44 per 1,000. The neonatal death rate is half the State rate. This the country women fully understand. The only services they cannot supply are a pathological department and a deep x-ray therapeutic department: but these can be obtained at near-by centres.

But I am not writing to praise the Victorian Bush Nursing Association, but, based on the knowledge gained, to ask some questions. Can a city, a university, a factory, or hotel become uneconomical and almost inhuman from being too large? Bata taught the world this lesson at Zlin, in Czechoslovakia. The huge institution becomes unwieldy from the administrative point of view, and in the case of hospitals from the human point of

view, and is far too costly. Do not all these facts apply with force to any organization? I find town planners who think a city should not contain more than 500,000 people. As the world has developed it is impossible, for example, to decentralize London to any great extent, or even Sydney or Melbourne, but the price paid is heavy—a lower birth rate and heavy mortality in the cities, not to speak of want of space, slums, and the like.

So I ask those who see what is wrong to put to themselves the question: What is the optimum size of any organization? Should, for example, a university be better if it housed nearly 5,000 students—a number being approached in Melbourne—than the huge institutions in the United States? To my knowledge university authorities in some of the magnificent universities in the U.S.A. realized the position many years ago, but found the task of limitation almost impossible, and I am afraid the Australian universities may find similar difficulties.

I may refer to a most remarkable fact which has come under my notice, and to which I drew attention at the Amsterdam Congress on Tropical Colonization, and also long before. Tropical Queensland is largely pastoral and agricultural, but does contain some small cities. The vital statistics in this region, whether birth rate or death rate, are better than in the rest of Australia. The high temperature has done no damage and tropical diseases are practically absent. In general in Australia the country birth rate is always greater than the city birth rate. To me the lesson is obvious, but the remedy is difficult.—I am, etc.,

JAMES W. BARRETT,

Honorary Secretary, Victorian Bush Nursing Association.

Melbourne, July 28.

Medical Planning

SIR,—Reading the correspondence and the reports that are available from the Medical Planning Commission and listening to medical conversations, it seems to me that attention is focused on what is to be done after the war without first considering what are the defects we wish to remedy and under what conditions the remedies will have to be applied. It is as if a number of doctors were consulting about a patient: one advises ultra-violet light treatment, another sulphapyridine, a third bleeding, and a fourth a winter in Egypt, all without having troubled to make a diagnosis or to consider what treatments may be available.

With great diffidence I suggest that first a list should be drawn up of those points concerning the profession or the public on which reform is desired. It is possible the Commission might agree on these points after discussion. Secondly, there should be an attempt to estimate what will be the after-war conditions under which the reforms will have to take place. About this agreement will be difficult, and whatever the estimates there will be much that has not been foreseen. But the attempt should be made none the less. A small point to serve as illustration. Much practitioner time is wasted giving certificates to chronic invalids. By a medical board system, on the lines of the Pensions Ministry, it should be possible to estimate the disability of these patients, if not permanently, at any rate for some time ahead.—I am, etc.,

Palgnton, Oct. 24.

ERNEST WARD.

Hospital Policy

SIR,—The Minister of Health has made an important declaration in Parliament on post-war hospital policy. The substance of this declaration is admirably summarized in the last few lines of your leader (October 18, p. 552) on Government hospital policy—namely, regionalization, co-operation between voluntary hospitals and local authorities, and Exchequer grants.

The Minister has every reason to congratulate himself upon receiving a very good "press" for his declaration of policy, although there may well be some misgivings and doubts in the minds of those who fear that too much control will be given to the local authorities by reason of the fact that apparently the State financial aid will be made through them and not direct to the voluntary hospitals or some recognized organization acting on their behalf, such as the British Hospitals Association, as has already been done in the case of the additional cost of nursing staff.

The Minister's policy has yet to be debated and approved in Parliament, and therefore it may still be capable of modification. In these circumstances it may be worth while considering whether any amendment of the proposals can be suggested which would meet with more general acceptance. In this connexion it should be borne in mind that to bring about close co-operation between the local authorities and the voluntary hospitals it is fully recognized by the Government that "to achieve the best results and to avoid a wasteful multiplication of accommodation and equipment it will be necessary to design such a service by areas substantially larger than those of individual local authorities." In other words, there must be a grouping together of a number of individual local authorities into regional areas. Clearly such regional areas must have regional councils, whose primary concern will be to translate into actual practice the principles underlying the Government's hospital policy.

Regional councils will presumably be constituted of representatives of the local authorities and voluntary hospitals of the area concerned. One of the first practical difficulties will be whether the numbers of such representatives upon the regional council are to be equal or based upon the numbers of municipal and voluntary hospitals or on the numbers of beds or on some other basis. It is obvious that in this direction there are endless possibilities for differences of opinion which alone may seriously prejudice the harmonious co-operation so eminently desirable and, indeed, fundamentally necessary to achieve success for the Government's policy. For this reason I suggest that it should be definitely decided that the representation of the municipal and voluntary hospitals upon such regional councils should be based upon an equal number of representatives, and, further, that in order to ensure, as it were, "fair play" for both parties, the Minister should take power, by Act of Parliament if necessary, to nominate in addition a certain number of representatives of the Ministry, altogether apart from those chosen to represent the local authorities and voluntary hospitals.

Many good reasons could be adduced for this suggestion. Let it suffice, however, to say that such a tripartite constitution is justified, first of all, by reason of the fact that the Government is providing financial assistance, presumably capital as well as maintenance, for both municipal and voluntary hospitals. Secondly, the presence of representatives of the Ministry upon regional councils would help to ensure that the Government's policy is being honestly and conscientiously carried out, and that the Minister through his own representatives is being kept in close touch with the development of the Government's policy throughout the whole country; and, finally, the presence of representatives of the Minister would go a long way toward the promotion of that mutual confidence and active co-operation between the local authorities and voluntary hospitals which is absolutely vital for the success of the scheme. If it became possible for regional councils throughout the country to be established on such a basis then it seems to me their position and influence would be immensely strengthened by making such councils the agency for the distribution of financial aid provided by the Government, and one would hope, in addition, financial aid provided from local authorities and charitable bodies such as King Edward's Hospital Fund for London and the Nuffield Provincial Hospitals Fund, as well as a host of smaller but none the less important funds.

It is tempting to enlarge still further upon the many advantages which would accrue to the community from such a suggestion as is outlined above, but in the meantime it would be interesting to learn the views of your many readers on that which has already been suggested.—I am, etc.,

Criccieth, Oct. 28.

FREDERICK MENZIES

Voluntary Hospitals

SIR,—The sweeping statement of Dr. G. Osborne (October 18, p. 558) that municipal hospitals are of lower grade than voluntary ones is not "true, kind, or necessary." In fact it merely demonstrates that his personal experience has so far been distinctly limited. In addition, however, it expresses a feeling which is regrettably prevalent among the general public, and which may have inspired Sir Frederick Menzies' first letter. Correspondents have already pointed out that municipal hospitals, any more than voluntary ones, do not

reach the same standards of efficiency, equipment, and staff. Most of the criticisms levelled at municipal hospitals are local and not inherent in the system, as Dr. Goodhart (p. 558) has explained.

There is, however, the one essential inherent difference between the two systems. The one type is municipal—that is, maintained by public funds, subject to Government scrutiny and audit, and governed to some extent by law. Thus the voluntary hospital can exercise some selection in admitting patients, but not the municipal one, so that "uninteresting" cases, especially of a chronic nature, gravitate to the latter.

Furthermore, the voluntary hospital, depending on free gifts, of necessity employs and relies on propaganda. This propaganda is directed to the increase of personal interest and often personal voluntary work. This personal interest is the great direction in which the voluntary system as a whole has such an inherent advantage over the municipal, and the interest begets influence. Mass interest of this kind is illustrated by the suppression of justifiable complaints against voluntary hospitals, whereas municipalities are popular targets. The influence of the voluntary system is illustrated in the Emergency Hospital Service, in which an extreme minority of senior administrative positions have fallen to members of the municipal services. It is this aspect which causes disquiet to members of the municipal services when plans for a future national hospital service are discussed.—I am, etc.,

St. Olave's Hospital, Rotherhithe, Oct. 21.

R. NELSON FORD.

SIR.—It is time that the idea of altruism in hospitals should be discarded. Their history shows that they never were either in origin or in their life altruistic. They have been throughout the ages instruments of exploitation. They are so yet. Their origin was the result of exploitation, when the Emperor Claudius started them to patch up for further service his broken slaves. Except that Claudius has changed from time to time to other agents, their function remains to-day the same. That being so, a sewage scheme holds as much altruism as a hospital.

The voluntary hospital is supposed to treat the sick poor. Now sickness treatment is a fundamental necessity of mankind. It should therefore be regarded as a duty like dealing with sewage. Who are the poor? A man is poor either because he is paid an inadequate wage by an employer or, having a sufficient wage, he wastes it. Hospitals therefore bolster up either a bad employer or a bad employee. The voluntary hospital as an instrument of exploitation has been used by kings, emperors, the Church, big business, the politicians, and a section of the medical profession. It is now in its death throes, as the man in the street is awakening to the real meaning of altruism.

The rate-supported hospital has therefore risen on the same rotten foundation as has a sewage scheme. It removes the terrible idea of charity in the treatment of sickness and will eventually replace the voluntary hospital. What a travesty of Christianity it is to see the shepherd wrapped in the fleeces of his flock enjoy the amenities of a private nursing home when sick, while his ailing shorn sheep brave the austerities of a public hospital! I admit that the rate-supported hospitals may have certain flaws inseparable from the political atmosphere about them. That seems inherent in all politics, but the courts so far have been able to prune them when too exuberant. We here in Glasgow are busy at present. We have made a good start, and if we go on as we are doing an increasing number of the elected of democracy will be evacuated to more congenial surroundings.—I am, etc.,

Dennistoun, Glasgow, Oct. 21.

JAMES COOK.

The Art of Surgery

SIR.—The distinction drawn by Dr. Frank C. Eve in your columns (October 25, p. 593) between two classes of surgeons, as he sees them, is most intriguing. He says a Class A surgeon practises surgical artistry, whereas Class B is a surgical tradesman. If the distinction could be hammered into all surgeons of all classes it would have the effect of changing many Class B surgeons into Class A surgeons, with great benefit to their patients and to themselves. Such is my faith in human nature.

The surgical artist is one who, when asked to perform an operation, however trivial or serious, thinks along clear lines

of the approach to the patient, the steps of the operation, and the benefit likely to come to the patient. He never gives a thought to the benefit likely to come to himself, except that he may increase his skill for the benefit of the next patient. His mind is a blank about the fee. The surgical tradesman, on the other hand, is alive from the first to the financial reward. He sinks, I fear, the patient's benefit to second place. Such a man never advances the art of surgery by any improvement in technique or theory. He is mundane and no adornment to his job. Whole towns are full of the Class B kind, brought into being, perhaps, by a pioneer surgeon of a past generation or by the general atmosphere of commercialism of the town; but whole towns are, thank God, full of the Class A kind. But among the Class B kind the practitioner who wants the best for his patient can find the surgical artist if he will look.

Here is another point. Every man who "goes in" for surgery does not become a surgeon. Before any man is permitted to sit for a higher surgical qualification, which he hopes will bring the surgery to him, he should go before a surgical "board" of the Royal Colleges and have a test in manual dexterity. It would be quite easy to devise suitable manipulations. Thus would clumsy men be eliminated, for if they go on I believe they become the surgical tradesmen—men working under difficulties, straining to reach the same skill as the artist.

It goes without saying that all surgeons of all classes, and no less physicians, should aspire to be Class A, and if they find themselves drifting should take themselves firmly in hand.—I am, etc.,

Great Malvern, Oct. 25.

A. C. DEVEREUX.

Reaction after Transfusion

SIR.—The cause of reactions following transfusions in many cases remains obscure. It has been suggested that in some instances at least the fault is in the recipient rather than in the donor's blood. The following observations favour this hypothesis. Blood from the same bottle, using the same administering unit, was given to two patients; one had a severe rigor, the other had no reaction. For obvious reasons such an experiment is not easy to arrange; it therefore seems worthy of record.

The first patient (Case S) had a subphrenic abscess and developed an empyema. The haemoglobin prior to transfusion on September 5 was 48% and his red blood cell count 3,900,000 per c.mm.: blood group O (IV). Cross-matching of the blood was not done. A transfusion was started with stored blood (Group O (IV)) at a rate of 40 drops a minute. Following our usual custom, the last two feet of the tube conveying the blood were warmed on a hot-water bottle enclosed in a woollen cover (temperature unknown). After approximately 150 c.cm. of the blood had been run the patient had a severe rigor lasting twenty minutes. The temperature was 101° F., and he was severely ill, requiring the administration of oxygen.

Less than fifteen minutes after stopping the first transfusion, the same bottle of blood and administering unit, with the exception of a clean needle, was set up for a second patient (Case B). This patient had a carcinoma of the bladder with severe haematuria. He had already had several transfusions of stored blood without ill effects. His group was O (IV) and cross-matching of the blood was not done. Prior to transfusion his haemoglobin was 34%, and his red blood cell count was 2,220,000 per c.mm. The blood was given at approximately 40 drops a minute. The remaining 390 c.cm. were taken by this second patient without ill effects, the haemoglobin rising to 40%.

It is of interest to note that the first patient (Case S) had another transfusion of fresh blood, given slowly (40 drops a minute), on September 17. This caused a severe rigor after ten minutes. On September 26, when his haemoglobin was 43%, he took half a pint of stored blood (ten-day-old) given quickly without any ill effect. When his general condition had deteriorated further he had another severe rigor following a transfusion with stored blood given slowly (40 drops a minute) and died six hours later. His death was in no way due to the transfusion, as he had had a long and exhausting illness associated with a liver abscess and large empyema.—I am, etc.,

R. D. N. BISSET, F.R.C.S., D.A.

Park Preston Hospital, Basingstoke, Oct. 27.

Wound Shock: A Heated Couch

SIR,—The whole question of shock seems to be very obscure, but everybody is agreed that a shocked patient is cold and that it is very important to get him warmed up again. If a patient is to be warmed at all it seems only sensible to warm him at once and to warm him quickly. There appears to be no doubt that if a man is chilled by exposure, without any injury, he can restore his own warmth to a great extent if given a reasonable chance. But if a man is wounded his heat-regulating mechanism is put out of action and he cannot restore his own heat: he must be heated. If the patient is wounded and also chilled by exposure his condition soon becomes desperate, and it will be a question whether he can be heated up quickly enough to save his life.

I want to suggest to those responsible for the disposal of air-raid casualties that as a general rule cases should not be sent direct to hospital; they should be sent to a near-by first-aid post to be treated for shock until they are fit for operation. The primary purpose of the F.A.P. should be the treatment of shock, and it should be equipped with everything required for the purpose. It is easy enough to heat a patient quickly if electrical gadgets are available, but it must be assumed that in an air raid the electric current and the gas supply will be cut off. The problem is to get some heat underneath the patient: an oil stove under the stretcher is much too dangerous and metal water-beds are unobtainable. I beg to submit the following improvisation.

A table is built to carry the standard stretcher; in the middle of the table-top a well is made to hold five petrol tins lying on their broad sides. The well is lined with blankets, and the tins, filled with boiling water, are covered over with blankets. A few inches from the corners of the well slots are cut to take the four legs of the stretcher; these slots make sure that the patient is well down on the petrol tins and that the stretcher is always in the right position.

It is essential that there should be a good supply of hot blankets; it is futile to put a patient into cold blankets, and it is not possible to heat up enough blankets after the "alert" has sounded. There must be a cupboard heated by hot-water pipes in which blankets can be kept always warm. That is the first requirement. When the "alert" sounds the warm blankets can be made hot by putting hot-water bottles among them. More blankets can be heated by putting a pile on the hot petrol tins, with an electrically heated cradle over them—so long as the current lasts. If the current goes off the patient, wrapped in hot blankets and lying on five petrol tins filled with boiling water, is surrounded by rubber hot-water bottles. The patient requires careful watching to see that he does not get too hot. A small electric fan to play on to the patient's face is a very pleasant (and perhaps valuable) extra.—I am, etc.,

R. L. KITCHING.

Welberby, Oct. 24.

Organization of E.N.T. Department in E.M.S.

SIR,—I fully endorse the article by Mr. V. E. Negus (October 11, p. 519) and the letter by Mr. Somerville Hastings (October 25, p. 594), which call attention to a weakness in the emergency hospital services. There is, I am fully aware, a keen desire on the part of the Director-General and those working under him to secure the maximum efficiency in these services, and yet in the ear, nose, and throat departments of these hospitals beds are wasted daily, and Service men remain in hospital for weeks on end with inadequate treatment. I do not feel that the administration have yet fully appreciated these facts, but I seem to detect a dawning interest in the matter. May it bear fruit.

There are a number of efficient surgeons available, but the instruments provided are unsuitable and inadequate, while those required in the wards for dressings are almost unobtainable. There is a grave shortage of nurses trained in E.N.T. work who are capable of doing dressings under illumination and can see what they are doing.

May I make the following suggestions? Operative work should be concentrated in one or more E.N.T. centres in each region. In these centres a full modern set of operative instruments should be supplied, all surgeons in the Region should be allowed to operate there, and all cases, save those unable to be moved, should be concentrated there for operation. We

should then no longer hear of an E.N.T. surgeon being dispatched thirty miles to an outlying hospital to perform one tonsillectomy.

Further, the present system, adopted under advice, of supplying a fixed, restricted set of operative instruments, many of which are archaic, to any hospital where an E.N.T. surgeon is working is uneconomic. I advocate a full set of E.N.T. instruments to the centres and no operative instruments to individual hospitals. If any operation had to take place elsewhere it would be open to the surgeon to borrow from the centre or to take his own. It is obviously impossible to supply a full set to every hospital, and anything less is useless.

I consider the position of treatment in the wards to be most unsatisfactory, and it is here that time, and therefore money, are badly lost. In every modern throat department there is a treatment room equipped with illumination, sterilizers, and instruments for diagnosis and treatment. There is an urgent need for the provision of such facilities in greater or less degree in every E.M.S. hospital. If the treatment room is efficient and under the care of a keen and properly trained sister, the number of cases requiring operation will be greatly reduced. I should like instruments for diagnosis and treatment, which are relatively few in number and inexpensive, supplied to every E.M.S. hospital at which an E.N.T. surgeon attends, and these should be solely allocated for use in the wards.

There is too little effective treatment and too much operative work; an operation is only justified under war conditions if it will enable the patient to return to his unit a reasonably fit man. Too often his stay in hospital after operation is terminated by his being boarded out of the Army.—I am, etc.,

Edgbaston, Oct. 28.

MUSGRAVE WOODMAN.

Possibility of Malaria in Britain

SIR,—Though there is evidence that cases of indigenous malaria may have occurred in this country sporadically until fairly recent years, no malarial outbreak of importance of either indigenous or foreign origin has been reported since that of 1917-18, when 330 civil and military cases of benign tertian were contracted following the return of groups of malaria-infected soldiers from the Near East. Conditions in some parts of our country at the present time are, in respect of the epidemiology of this disease, not unlike those which preceded the 1917 epidemic (Reports to the Local Government Board). When there is close association between the malaria carrier, the anopheline mosquito, and the susceptible individual there is reason to expect new cases of the disease. If, as could happen reasonably enough in a country where malaria is almost unknown, these first new cases were missed or insufficiently treated, there would be a rise in the endemic index of that area, with, it need hardly be said, possible serious results. The object of this letter is to draw the attention of general practitioners and Service medical officers in potential malarious districts to the fact that cases of malaria among men who have never been abroad are more likely to arise now than at any time since the close of the last war.

Of the three main links in the chain of malarial propagation two are perennially present in Britain—namely, the potential malaria-carrying anopheline mosquito and the susceptible individual; while the exigencies of war have intervened to provide the missing link, the malaria carrier, on the absence of which our insular freedom from the ravages of malaria has principally, though not wholly, depended. With regard to the malaria carrier, it is common knowledge that there are many thousands of men in this country at the present time who have fairly recently come from Eastern European and Southern European countries where malaria is endemic or from tropical and sub-tropical parts of the Empire. Many of these men have undoubtedly suffered from malaria, and a number will continue to be subject to recurring attacks and carry gametocytes in the peripheral blood from time to time. Though lacking concrete evidence on the proportion of men who come from either of the above categories, yet the known facts relating to the course of this disease justify the assumption that some of them may harbour infection.

Anopheles maculipennis is not only the most numerous and widely distributed species of the three British anophelines which are known to be capable of transmitting malaria, but is, from

of its habits, the most likely to be incriminated. Work by the Continental entomologists, Hackett, Martini, and Missiroli,¹ has shed light on the previously obscure problem of the high incidence of malaria in some districts in northern latitudes and the comparative freedom of others, though *A. maculipennis* was present in both. The problem was elucidated by the demonstration of several varieties of *A. maculipennis*, two of which, with widely differing habits, have since been identified in Britain (Marshall²). This discovery is of peculiar importance in connexion with the spread of malaria in temperate climates, and, further, it explains certain perplexing features of the 1917-18 outbreak. The two British varieties are *atroparvus* and *mesaeae*. The former breeds in coastal brackish waters. It is only partially hibernating and seeks blood meals throughout the winter in the warm ill-lighted buildings which it frequents. The latter is found mainly in inland districts and passes through a stage of complete hibernation, before which it bites voraciously to build up the fat body. If at this juncture it becomes infected it can continue infected throughout hibernation and transmit sporozoites when it seeks a pre-oviposition blood meal the succeeding spring. Fortunately, if animals can be obtained it does not readily attack human beings. In the case of *atroparvus*, on the other hand, conveyance of infection to individuals may continue throughout the winter, not only because the insect remains active, but because "the parasite may develop in mosquitoes which live in heated houses even in places as far north as Archangel, and so the disease may be conveyed in the coldest weather." (Rogers and Megaw.³)

It is clear that, given a number of malaria carriers and a close association between them and the female mosquito such as is possible in the Nissen huts in which soldiers are housed and in which a warm humid atmosphere is maintained, conditions are thereby provided which are favourable to the infection of the anophelines and to the transmission of the parasite to simultaneous or subsequent non-infected occupants. The *atroparvus* variety is obviously the more dangerous of the two, and particular care should be exercised in coastal and estuarine districts if soldiers from malarious parts abroad are stationed there. *Mesaeae*, however, should not be overlooked, and in that connexion it is worthy of note that I have recently identified females of *Anopheles maculipennis* in the vicinity of a camp in which Indian troops are quartered.—I am, etc.*

Practical Results of Diphtheria Immunization

SIR.—What immunization can accomplish in combating diphtheria is shown by the remarkable drop in incidence in Brisbane. The local authority of Brisbane, the city under review, has an area of 375 square miles and a population of 55,520. In January, 1938, I decided to make every effort to speed up the council's free immunization service. I used every available means to impress upon parents the importance of aving their children—especially their children of pre-school age—immunized. The response exceeded my most sanguine expectations.

In the three years and seven months period—namely, from January, 1938, to July 31, 1941—I have fully immunized 22,912 children. This rate of immunization in Brisbane, which is averaging approximately 6,400 per annum, is, in the period under review, considerably in excess of the birth rate. To this must be added an unknown but considerable number of children immunized by private practitioners, and I am pleased to be able to state that as I write the response of children is greater than ever. Records disclose that at least 70% of this total are children of pre-school age. By educative methods the task has now been reached in Brisbane when the vast majority of parents realize that they owe this simple duty to their children.

The maximum incidence of the disease occurs during the second, third, and fourth years of life, and as large numbers of immunized children of this age group are appearing every

day in increasing numbers in Brisbane, the incidence of the disease now shows the anticipated spectacular fall. Here are the figures for this period:

Population and Diphtheria Cases				
	1936	1939	1940	1941 (7 months)
Population ..	325,890	326,000	333,560	335,520
Cases ..	459	508	231	156

Diphtheria in recent months has reached epidemic proportions in some cities, but Brisbane, which now has 75% of its susceptible child population immunized, is safe from such an eventuality, and with parents co-operating so wholeheartedly with the council's department of health in its sincere attempt to eradicate this serious disease from their midst, a diphtheria-free Brisbane is not far distant.—I am, etc.*

Medical Officer of Health.

Increase in Tuberculosis

SIR.—Houghton, in his paper on the blood picture in tuberculosis (*Tubercle*, November, 1935), quotes the work of Murphy, Sturm, and Ellis, who found that they were able to increase resistance against experimental tuberculosis in mice by artificially increasing the number of lymphocytes by means of splenectomy, or, more especially, heat. Conversely, mice exposed to x rays in sufficient dosage to produce atrophy of lymphoid tissue were found to become more susceptible than normal to tuberculosis. Also, Taylor (*J. exp. Med.*, 1919, 29, 41) showed that a relative and absolute lymphocytosis occurred in the majority of persons he examined before and after a course of heliotherapy during the summer months. These observations are supported by clinical evidence that healing in tuberculosis is associated with increase of lymphocytes in the circulation, and that failure of resistance is associated with lymphopenia. I have published (*Journal*, November 16, 1940, p. 660, and January 11, 1941, p. 65) clinical observations purporting to show that the lymphatic glands act as a barrier against haematogenous tuberculous infections. Therefore any factors tending to produce lymphocyte leucopenia would lower resistance to tuberculosis. Vitamin-B deficiency is such a factor (Sampson Wright, *Applied Physiology*, 1937). Associated also with vitamin-B deficiency is impairment of absorption of fat from the small intestine. This in turn would favour deficiency in the absorption of vitamin A.

Thus another argument, if another were necessary, can be produced for the consumption of wholemeal bread, which has been recommended by the Government. Also, if it is true that heat and light promote lymphocytosis, confirmation is found for the value of heliotherapy in the treatment of non-pulmonary tuberculous lesions, and an argument is constituted for the use of light-treatment centres by the public during the months when black-out conditions are at their worst. Heat in the form of infra-red rays, as well as ultra-violet light, should be applied at such centres, and this work would be done more safely if it was brought within the purview of the tuberculosis officer.—I am, etc.*

Braintree, Essex, Oct. 20

M. C. WILKINSON, M.B., B.S.

Treatment of Scabies

SIR.—Scabies may be attacked from two aspects: that of the dermatologist, who looks for a cessation of clinical symptoms, and that of the entomologist, who sets out primarily to exterminate the parasite which causes the disease. I consider that dermatologists and entomologists must work in collaboration (and any results that I as an entomologist have been able to obtain are in a great measure due to help and advice freely given by dermatologists); but surely the first thing we must ensure is that our treatment is really killing the sarcoptes in all its stages—that is, the problem should first be attacked from the entomological aspect. Then if (as is the case) it is found that the parasitic infection can be exterminated without a cessation of all clinical symptoms, the dermatologist must carry on from that point. But to try, in the first instance, to cure the symptoms while ignoring the parasite which causes the disease is surely to put the cart before the horse.

The question of whether or not it is always necessary to find living or dead acari has become somewhat confused. Where the treatment of scabies is part of a research programme, then

the worker must surely be expected to be able to demonstrate exactly what his treatment is doing to the parasite. It is because research workers have been so unfamiliar with sarcopites that so many conflicting results regarding treatment have appeared. It should be possible for the practical man who has to treat the disease to follow the directions of the research worker with the certainty that the disease will be cured at any time or in a known proportion of cases. The ability of the research worker always to find the parasite should save the practical man from this trouble, but the practical man must refrain from calling his results "research" and publishing them for the confusion of others.

New methods have at times been advocated as a result of experiments using far too few cases as well as on insufficient evidence. It is at present premature for me to describe most of my work on this point, but I believe that no new method should be advocated unless it can be shown that in at least fifty cases it has exterminated every parasite and has eventually put an end to the clinical symptoms. I may state that I have found mites alive after treatment of the patient at reputable centres with many different methods, including benzyl benzoate.

While it is difficult to produce evidence to show that a new method is entirely successful, it is much easier to show that an unsatisfactory method is likely to be unsuccessful, for if 100% failure to cure is obtained in even a small number of cases it is obvious that it is hardly worth while continuing its use. This point may perhaps be illustrated by reference to the use of sulphur taken internally as advocated by H. M. Berncastle.¹ The following experiments were made. (1) Two infected volunteers were each fed rather more than 10 grammes of sulphur daily for ten days. This had a slightly purgative effect at the beginning, but the men soon recovered. At the end of ten days both men were more heavily infected than at the start—that is, it was possible to observe a larger number of parasites on their bodies and all stages of the mites appeared to be entirely unaffected; (2) Three uninfected volunteers ate 10 grammes of sulphur daily for seven days. They were then experimentally infected with sarcopites and continued to eat sulphur for three more days. Biopsies made on the tenth day showed that the mites had burrowed normally and had also laid eggs which were developing in a normal manner. These experiments seem to be sufficient to indicate that this method cannot have a universal application.

Finally, I should like to make a protest. Certain people have accused me of writing, and your *Journal* of publishing, a statement that scabies is "a venereal disease." Reference to my article² will show that I state that I believe the disease to be "normally transmitted by personal contact either of a slight or of a venereal nature." I still hold that view, but to say that it implies a belief that scabies is "a venereal disease" is surely a gross misrepresentation. Non-venereal transmission by personal contact, particularly among children, is probably much more frequent than venereal transmission, but among young adult males in the Army venereal transmission, though very far from universal, appears to account for a certain proportion of the cases.—I am, etc.,

Sorby Research Institute, Sheffield, Oct. 23.

KENNETH MELLANBY.

SIR,—I was particularly interested in the article by Dr. Dorothy L. Carter (September 20, p. 401), because since March I have been treating cases of scabies in one of the Colchester first-aid posts with a sulphur shampoo. The treatment consists of the usual bath and scrubbing, but afterwards the patient is thoroughly shampooed all over with a shaving brush with a shampoo of the following composition: sulphur praecip., 30 grains; glycerin, 4 minims; soap spirit, 120 minims; aq. rosae, ad 1 oz. A well-known firm of chemists makes this shampoo for me at a cost of 2s. 6d. for a 40-oz. bottle, and approximately 1 oz. of the lotion is needed for one treatment of an adult and 1/2 oz. is sufficient for most children. Each patient is given two treatments on consecutive days.

From March 29, 1941, to September 30, 1941, 116 persons have been given this treatment. The result has been that within a fortnight six persons have returned for further treatment owing to the recurrence of itching. It appears to me that a fortnight is a reasonable limit to set. After a fortnight fourteen

persons have returned. The majority of these were undoubtedly reinfections, as they returned months after the first treatment.

The sulphur shampoo is allowed to dry on the patient and he puts clean clothes on over the shampoo when dry. There has been no trouble from sulphur dermatitis even with quite tiny children. The usual disinfection of bedding and clothing is carried out for each case. I am inclined to think that this method is probably simpler and cheaper than any other so far suggested, but the important factor, as in all other methods, is thorough treatment by trained personnel.—I am, etc.,

Health Department, Colchester, Oct. 29.

W. F. CORFIELD.

Diabetes and Chronic Nephritis

SIR,—I should be glad to know if any of your readers have had experience with the action of mersalyl in the treatment of diabetes mellitus. I am sending particulars of a case, which has recently been under my care, in which the use of mersalyl has had a decidedly beneficial effect. I should be glad to hear if anyone can throw a light on what its action is.

The patient is a woman aged 66 suffering from diabetes mellitus and chronic nephritis. She was on insulin soluble 45 units each evening, and zinc-protamine-insulin 45 units with insulin soluble 25 units each morning. In spite of this dosage her urine always gave an orange reaction to Benedict's test. She had increasing ascites and oedema of the face and legs, and did not respond to diuretin, urea, or cardophyllin. After a microscopical examination of her urine, which showed only a few epithelial cells and a few hyaline casts, I decided to give her an intramuscular injection of mersalyl (1 c.cm. diluted to 10 c.cm. with sterile water). One hour before this injection she was given ammonium chloride 30 grains in 1/2 oz. water. Her fasting blood sugar before the injection was 0.332%, and a specimen of urine was taken and gave an orange reaction to Benedict's test and contained albumin +++.

Five hours after the injection a further specimen of urine was tested and no sugar or albumin was found to be present. Insulin was stopped and the urine was sugar-free for the next forty-eight hours. The patient's general condition showed a remarkable improvement; the oedema diminished, and the output of urine was doubled during the following week; it rose to 58 oz. during the twenty-four hours immediately following the injection. At the end of forty-eight hours the fasting blood sugar had fallen to 0.266%. Three days after the mersalyl the urine again gave an orange reaction to Benedict's test, and although the original doses of insulin were resumed the reaction remained orange. A second injection was given eight days after the first, with a resultant output of 92 oz. of urine in the following twenty-four hours. A specimen of urine after this second injection gave a green reaction to Benedict's test, and further tests have also given a green reaction.

Now (nine days after the second injection) the improvement in the patient's general condition has been maintained; she feels, as she says, "a new woman."—I am, etc.,

London, N.21, Oct. 17.

TADEUSZ MARKOWICZ.

Treatment of Varicose Veins

SIR,—Mr. R. T. Payne's exhaustive article on varicose veins (October 18, p. 533) contains some remarkable statements. He tells us that "minimal" operations—i.e., "ligation at the saphenous opening and possibly at one other site"—"even when combined with subsequent injections, rarely lead to complete obliteration"; that "in a case of average severity . . . operation has to be carried out at five or six sites"; that "a mass of tortuous veins . . . calls for free excision," while certain other cases demand "a more extensive excision." And, finally, that "care is needed in planning incisions," and "there is nothing to suggest that surgery should be maximal." By the twelfth to the fourteenth day, it is gratifying to note, the patient "should be able to walk short distances." But is this "sub-maximal" assault really justified? Can satisfactory obliteration only be achieved by totalitarian methods?

The simple method of ligation at the groin, with a single injection of ethamolin at the time, preferably down an intra-venous catheter, has given entirely satisfactory results, both in peacetime and under the severer conditions of war. The patients can travel within eight to ten days; and they do not require "daily injections" four weeks after operation.

¹ *British Medical Journal*, October 18, 1941, p. 560.

² *Ibid.*, September 20, 1941, p. 405.

"Care is needed," undoubtedly; but it should perhaps be exercised before announcing that such reliable "minimal operations should be avoided."—I am, etc.,

Oct. 24.

C. R. McLAUGHLIN.

Status of the Ship Surgeon

SIR.—Will you allow me somewhat belatedly to refer to some points raised by Dr. James Prendergast (June 14, p. 904) in his letter on the above subject, which I have been unable to read until now owing to absence at sea.

With regard to the objectionable "Voyage Regulations," it seems a pity that those who were responsible for drawing up these did not follow the good example set by the U.S. authorities to meet similar conditions in the last war. At that time those of us who were ship surgeons on vessels carrying American troops were given recognition by the U.S. Government as well as a certain remuneration, in return for which we were asked to advise and guide the military medical officers in their ship-board duties.

In practice things usually work out better than might be expected from a study of the regulations. Actually these can be traversed by the master of the ship, who is responsible for the safety of his crew and ship, and he can ask the ship surgeon to carry out any duties he considers necessary for this purpose, even when this involves the examination of soldiers who may be suspected to be suffering from a serious infectious illness. Such an examination is, of course, carried out in conjunction with the S.M.O., and up to the present I have found the military medical officers only too willing to co-operate for the comfort and well-being of all those on board. On several occasions I have been asked by the S.M.O. to operate on soldiers suffering from appendicitis or, to assist him while he operated, and in turn the S.M.O. has always been glad to give an anaesthetic when I found it necessary to operate on one of the crew. When, as a result of enemy action at sea, we had a fairly large number of casualties, the military medical staff and the ship's medical staff worked as a unit. This, of course, is no excuse for the regulations referred to, and Dr. Prendergast has done well to draw attention to them.

In the course of nearly thirty years of service at sea I have never been able to take the view that the duties of looking after the crew were trifling, and I have on more than one occasion known disastrous results happen owing to that view having been taken. Still, I think Dr. Prendergast merely wishes to say that he would like to feel he was doing more. As to the dullness when work is not plentiful, I am afraid nothing much can be done about it. One of the attractions of a medical career at sea is that it provides one of the few escapes for the doctor of a studious turn of mind who is willing to sacrifice a certain amount of financial remuneration for the leisure that will allow him to prosecute his studies, whether scientific or cultural, and at the same time enable him to make up in the quality of his work what it lacks in quantity. I hope this opportunity will long remain open to members of the profession, though I should be the last to deprecate an increase in remuneration.

It is regrettable, I think, that this opportunity is not more widely utilized by men of the required temperament and mental qualities. Our profession would be all the better for being leavened by members who had the time and the inclination to make a serious study of subjects outside the range of ordinary medical or surgical work. Some time ago I read a correspondence conducted on something like equal terms between a leading mathematician of this country and a doctor. The latter was thanked for having pointed out an error in the published work of the former, the work in question dealing with one of the most recent developments in mathematical theory. The doctor, a former ship surgeon, had acquired his mathematical equipment in the intervals between seeing patients at sea. One could cite other instances in support of the view that a ship surgeon's recompense is not to be measured entirely by financial standards. This is not to be construed as a plea in favour of cheap labour or its equivalent in medical practice.

As to status on board, without belittling the necessity at times for extraneous aids, it can hardly be denied that an important part of this status is created by the ship surgeon himself and carried with him from ship to ship.—I am, etc.,

Oct. 25.

A. GARDNER, M.B.

Science and World Order

SIR.—I refer to Dr. A. P. Cawadias's letter (October 25, p. 592) dealing with the British Association's conference on the above subject, in which he states that the conference was not international, that no place was made for foreign delegates, and that on the whole few Allied and foreign scientists participated. The facts are as follows. Of the chairmen of sessions four were foreign representatives and two British. Out of sixty speakers, apart from chairmen, twenty-six were British scientists or technicians: twenty-seven were foreign scientists (either working now as such or formerly having done so), of whom ten were nominees of foreign Governments or institutions now in this country; six were British statesmen or Government servants: one was a writer.

If this conference, the first attempt of its kind, leads to more precise discussion of particular questions at subsequent meetings, whether of the British Association or other bodies, one of its principal objects will have been achieved. A committee of the Division for the Social and International Relations of Science is now inquiring into every concrete proposal made at the conference, endeavouring to inform itself, in respect of each, of what action, if any, is being taken now, or of what should be done, by whom, and how. The extremely important questions of starvation and epidemics referred to by Dr. Cawadias and by at least four speakers at the conference (not one only, as he states) are among these.—I am, etc.,

London, W.I. Oct. 28.

O. J. R. HOWARTH,
Secretary, British Association

Mobile First-aid Posts

SIR.—Dr. C. Grantham-Hill (October 25, p. 594) has stated the textbook conditions under which a mobile unit would go into action. In actual practice there are rarely sufficient casualties in a very restricted area in a town (with hospital near) to warrant setting up a mobile post. So if these conditions were adhered to doctors of mobile units would not often be called upon.

Our experience has indicated that wherever there are a few casualties a mobile unit doctor should go with one or more of his personnel in a car carrying packs of dressings, etc., a doctor's emergency bag, and a few long splints inside, and, in the boot, A.T.S., blankets, hot-water bottles, vacuum flasks of hot water and beef extract, all the latter for that highly dangerous condition, shock. The doctor then goes from "house to house." (Elastoplast dressing-strips are not an official issue, but they save a lot of time!) But if a mobile van has to turn out, I would suggest that it should contain two table-tops (with trestles) on which to lay out dressings, etc., and from which to work. For speed in laying out, all the dressings needed for these tables can be stored conveniently in the top divisions of the A2 box.

Dr. Grantham-Hill's well-equipped van for washing and treating patients is doubtless very useful for rural districts far from hospitals, but in the towns our chief aim is to rush patients to hospital with the maximum speed, where the wounds are cleansed, etc. Incidentally, the dirt is so embedded that it would be impossible for the mobile doctor to get it out.

Finally, mobile unit doctors should make it a duty to spend an hour every month or so with the heads of report centres, discussing matters of common interest. It is amazingly helpful to both parties.—I am, etc.,

Maurice E. J. Packer,
Oct. 25. M.O. in Charge, No. 1 Mobile Unit, Clifton, Bristol.

SIR.—Your correspondent Dr. Grantham-Hill might be interested to know that in the town where I live we have three mobile units built on the lines he describes. They are converted buses, originally designed to carry about 30 people. I believe we are indebted to our medical officer of health for the idea. Such a unit certainly does relieve one of the anxiety of finding suitable premises for working in during a raid. My unit is roomy, well lighted, with operating table, sterilizer, and large water-tanks (these last on the roof). So far my unit has been in use during one (our chief) raid, and, with all modesty possible, I think we were well worth our keep. There is one

point which we found needed altering: a portable light-trap is essential; work cannot be carried on when, every time the door is opened, workers are thrown into darkness inside.

I gather that Dr. Grantham-Hill has had his unit frowned on officially. I, too, detect a certain chilliness in the atmosphere whenever a mobile unit is mentioned, and I am sure our reception would be more cordial if the original Government idea were modified on the lines Dr. Grantham-Hill indicates. In the eventual merger of A.R.P. and Home Guard medical services (surely a very likely merger in a long war), our travelling units may, I feel, earn the gratitude and admiration of the Ministries concerned.—I am, etc.,

Doncaster, Oct. 28.

ROBT. W. L. WARD.

First Aid to the Injured

SIR,—I have read with interest Dr. J. C. Hodgson's letter on "First Aid to the Injured" (October 25, p. 595), in which he suggests that simplicity, flexibility, and improvisation are required in wartime, and considers that a special pamphlet on "First Aid in Time of War" should be published. Is this really necessary? At the time of a heavy air raid these characteristics are certainly required; nothing but simple methods can be used in removing casualties from burning and falling buildings, usually at night, such methods being the steadying and supporting of fractured limbs by bandages, applying tourniquets for severe haemorrhage, and trying to keep the casualty warm. After that the personnel of the post or point will deal with the cases in a deliberate and orthodox manner. All posts and points have a medical man in charge, I believe, or obtainable at call, and he will supervise the best treatment available until the cases are removed by ambulance.

Dr. Hodgson remarks that the tourniquet is not foolproof; I quite agree, but it is more important and often much more urgently required in wartime than in peacetime. It should be of the simple rubber-band type, easily made from the inner tube of a motor-car tyre cut on the spiral.

In my opinion too much has been made of this so-called "wartime first aid"; it is practically all in the 1940 edition of the "Red Cross Manual," although certain things require stressing in lectures.—I am, etc.,

HOWARD M. STRATFORD, F.R.C.S.Ed.

Beckley, East Sussex, Oct. 25.

SIR,—The letter under this title from Dr. John C. Hodgson merits a reply. In my opinion Dr. Hodgson is confusing the issue between "first aid to the injured" and "the after-care of the injured," as he postulates an interval of days between the injury and professional attention. If this is to be so "during a period of invasion, especially in rural areas," then obviously it follows logically that the scope of training should be increased to cover such an eventuality, and I have been asked many times by my own personnel since the war to widen and deepen the training for this very reason.

It is my experience over a great number of years that first aid and casualty work appeal to a very small percentage of the population, and that those who do take it up do so seriously and become experts in their own particular subject and are very keen to add to their knowledge. It takes years to make a really efficient "first-aider," and it is quite useless to expect to produce an efficient casualty service by giving short courses on first aid to the general public. I have done so and I know the result—a smattering of ill-digested knowledge, soon forgotten.

In my opinion a grave mistake has been made in not taking over every St. John Ambulance Division *en bloc* as a working casualty unit and reserving each member for that work. The result of not doing so in my own Division, where we have men, nurses, cadets, and a motor ambulance, is deplorable. Many of our fully trained members have been taken into services totally unconnected with casualty work, and thus all their training virtually wasted, while the few remaining struggle to keep the service going in a rural area liable to invasion.

At the present time there is much confusion in the civilian casualty service between mobile units, first-aid posts and points overlapping the work of the St. John and Red Cross. I would suggest: (1) That the St. John Ambulance Divisions be placed on a war footing and made responsible for all casualty services

in their own district; to organize such services without any interference from any source. (2) That adequate medical supplies be forthcoming to each unit without delay. (3) That each Division should act as a centre for the training of the public and services in emergency first aid, and at the same time give more extended training to those interested or responsible for any post where casualties may have to remain for any length of time.—I am, etc.,

RUPERT PALMER,
Divisional Surgeon, St. John Ambulance,
Lydd Division.

Oct. 26.

A National Health Policy

SIR.—More persons of higher income may become insured; a higher capitation fee may be granted. These actions may injure or benefit the profession, may ensure that illness is promptly treated and its duration shortened, but they will do nothing to reduce the onset of illness. A State Medical Service might be a benefit or a curse, but it, again, would not reduce the sickness incidence in the population. Neither the profession nor the public is at present in a position to deal adequately with such a radical change in the organization of its medical services. This is a debatable matter, and a large proportion of the medical profession is at present absorbed in the Services and unable to attend to a matter which will be vital both to them and to the public.

There is, however, a matter of greater importance to the public and the profession, which has scientific evidence and practical experience in support of its worth, which could and should be put in the front line of defence now and remain in the front line of maintenance in our post-war economy. I refer to the "Medical Testament" of the Cheshire Panel Committee. This practical demonstration of better health for the nation should be made a national policy. It has the support of Sir Albert Howard as an agriculturist, whose work won world-wide acknowledgment; and of Sir Robert McCarrison, an authority on dietetics second to none. Its practical application as a national policy would: (1) Reduce sickness by prevention, which is better than cure. (2) Increase the well-being of the whole population. (3) Reduce the hours lost to productive work and so increase our productive capacity. (4) Increase the quantity and quality of home-produced food to the maximum. (5) Reduce the drain on the country due to cost of medicines and sick pay. (6) Reduce the amount of work to be done by each practitioner without altering his panel, which is the equivalent of a higher capitation fee but without cost to the State. (7) Put agriculture on its feet and keep it there, with adequate wages and return on capital and with increased fertility and production from the soil. (8) Give a higher standard of health and living without an increase in the cost of living.

Probably many will say that all this is impossible. Let them read and think about the "Medical Testament" and the speeches made by Sir Albert Howard and Sir Robert McCarrison in support of that testament, and read, in addition, the former's *Testament of Agriculture*. They will then find that the way is there; we have only to make up the will.—I am, etc.,

Market Rasen, Oct. 26.

DUDLEY F. TORRENS.

The American Association for the Study of Goiter again offers the Van Meter Prize of three hundred dollars and two honourable mentions for the best essays submitted concerning original work on problems related to the thyroid gland. The award will be made at the annual meeting of the Association, to be held at Atlanta on June 1, 2, and 3, 1942, providing essays of sufficient merit are presented. The competing essays may cover either clinical or research investigations; should not exceed three thousand words in length; must be presented in English, and a typewritten, double-spaced copy sent to the Corresponding Secretary, Dr. T. C. Davison, 478, Peachtree Street, Atlanta, Georgia, not later than April 1. Dr. Arthur Chapman of Rochester, Minnesota, has received the award for the year 1941 in recognition of his essay entitled "The Relationship of the Thyroid and the Pituitary Glands to Iodine Metabolism and Extrathyroid Iodine Metabolism."

Obituary

The death at the age of 92 of Dr. NATHANIEL BENOLY, for over sixty years a member of the B.M.A., has removed a figure at once venerable and much beloved. His medical activity did not cease till July, 1939, when he had reached the age of 89. Even at so advanced an age he still retained extraordinary energy of mind, body, and spirit, literally looked and felt twenty years younger than he was, and rejected with scorn any suggestion of a well-deserved retirement. The secret of his devotion to his work was the love of a man for his fellow men, and in the East End of London, where he was in general practice during the latter half of his life, he will remain unforgotten by many. For not only was he a doctor of outstanding ability, whose diagnosis was remarkable and whose treatment was based on methods founded on long experience and unexaggerated application of modern therapy, he was also the friend of his patients, the cheerful, often witty counsellor: there must be many a man, and woman and child, too, to whom contact with "the old Doctor" meant a new and more hopeful beginning of life, both physically and spiritually. In his younger years he had travelled considerably in European countries and in South America, and his memories going back further in time than the memories of most, his conversation was often enthralling. He lived in retirement from the beginning of the present war, but except for the last few months, when his health declined, he retained his lucidity of mind, his gay serenity of spirit, and his love of books and men.

G. R. B.

The passing of R. M. LITTLER, F.R.C.S., severs a link with Whitehead, Japp Sinclair, and others who made the Manchester School famous. To both Mr. Walter Whitehead and Sir W. Japp Sinclair he had been house-surgeon. Coming to Southport over forty years ago, Littler was the first secretary of the Southport Medical Society, serving in that capacity for several years and later becoming president. In 1912 he was chairman of the Southport Division of the B.M.A., of which he had been a member for forty-six years. In 1905 he joined the honorary staff of the Southport Infirmary, and from 1924 to 1925 was chairman of the Medical Board. Retiring under the age limit he was appointed honorary consulting surgeon. Cultivating his garden in the broadest sense he found a corner in it for music and a very special one for horticulture. Unfortunately the years of retirement were marred by indifferent health. Of broad view and sound judgment, although at times a little mistrustful of his own ability, Littler's advice and help were often sought by and given to his medical friends, whose respect and affection he had in more than full measure.

W. A. M.

We regret to record the death of Dr. FERGUS MACANDREW DAVIDSON on October 9 at his home in Arbroath at the early age of 52. Born in Aberdeen, he was educated at Ashley School, Robert Gordon's College, and Aberdeen University, from which he graduated M.B., Ch.B. in 1914. He went to Arbroath in 1919, where his kindly and gentle presence soon endeared him to friends and patients alike. He was on the staff of Arbroath Infirmary, where he took a great interest in the electrical department. He was also medical officer for the parish over a long period of years. Dr. Davidson was untiring in his work among his patients, never sparing himself, and this took a heavy toll of his strength. He will be missed in many homes, and the memory he leaves behind him will be a fragrant one and that of a very gallant gentleman. In his infrequent spells of leisure his hobbies were art and philately. A member of the B.M.A. for well over twenty years, he is survived by his wife and by his daughter, who is also a member of the profession.

Dr. GEORGE ALEXANDER COHEN, who died in hospital at Edgware on October 16 at the age of 71, had been a coroner for more than thirty years. A native of Hull, he studied medicine at the University of Edinburgh, at St. Bartholomew's Hospital, and in Dublin, graduating M.B., C.M.Ed. in 1893. After

holding a resident post in London at the National Hospital for Diseases of the Heart he made many voyages as ship surgeon, and returned to London in 1906 to take up general practice at Green Lanes, Harringay. He then became a member of the Middle Temple and read for the Bar, and at the time of his call was awarded the Powell prize in common law and the prize in evidence and legal procedure. In 1910 Dr. Cohen was appointed a part-time coroner, and in 1916 he became full-time coroner for East and Central Middlesex. In his early years he was a keen volunteer, with a commission as captain in the Volunteer Battalion of the Middlesex Regiment; he had also been an instructor and lecturer at the Ambulance School of Instruction. He was a liveryman of one of the City companies and a keen supporter of the Arsenal Football Club.

By the death of Dr. JOHN GILFILLAN RONALD at Torwood Hall, Larbert, on October 22 Stirlingshire loses one of its oldest and best-known medical practitioners, who had been a member of the B.M.A. for nearly half a century. A student of the University of Glasgow, he graduated M.B., C.M. with commendation in 1892, and held a number of important posts during his long period of active work at Larbert. He was an authority on first aid and ambulance work and examined for the British Red Cross Society, which made him an honorary life member. During the last war he served with the rank of captain R.A.M.C.(T.A.), and at the time of his death he was a deputy chairman of the Stirlingshire Medical Recruiting Board, medical officer to the Carron Company, and visiting medical officer at the Camelon Fever Hospital. In 1934 Dr. Ronald was presented with a silver loving cup and a cheque for nearly £300 in gratitude for his medical skill, his devotion to his profession, his sympathy with suffering, and his generosity to the poor.

Dr. JOHN JOSEPH REDFERN, who died in retirement at Compton, near Winchester, on October 23, was born in Belfast in July, 1861, eldest son of the late Prof. Peter Redfern, M.D., of Queen's University. He had a distinguished career as a student in Belfast, winning a gold medal and scholarships in chemistry, anatomy, and physiology, and graduated B.A. with first-class honours in experimental science in 1881, and M.D. and M.Ch. with first-class honours in 1885. After postgraduate study in London, Vienna, and Berlin, Dr. Redfern settled down in practice at Croydon, where he became honorary physician to the Croydon General Hospital and later physician to the War Hospital. He had been a member of the British Medical Association for just over fifty years.

Dr. ALFRED SKIRROW ROBINSON, who was killed by enemy action last month, had been a member of the British Medical Association since 1899 and for some years took a prominent part in the public life of the North Riding of Yorkshire, serving both on the Redcar County Borough Council and on the North Riding County Council. Born at Leeds in January, 1871, he was educated at the Yorkshire College, Leeds, and Emmanuel College, Cambridge, which he entered with an exhibition from the Haberdashers' Company of London. He graduated B.A. in the Natural Sciences Tripos of 1892, qualified as L.S.A. in 1894, and took the Cambridge M.A., M.B., and B.Ch. degrees in 1896. At Leeds he was house-surgeon and resident anaesthetist at the General Infirmary and acted as clinical assistant to Mr. T. Pridgin Teale. Settling in practice at Redcar he became medical officer and public vaccinator for the Kirkleatham District. Dr. Robinson had been medical officer to the 5th Yorkshire V.A.D., and served during the last war with a temporary commission in the R.A.M.C.

E. Verrill and E. A. Lane (*New York St. J. Med.*, 1941, 41, 1186) record a case in a man, aged 55, who had been a typhoid carrier for the past thirty-six years, during which he did not infect anyone inside or outside his family so far as was known. Removal of the gall-bladder, which contained a gall-stone of unusual size, failed to cure the typhoid carrier condition. There appears to be no previous case on record during the last ten years of the association of the carrier state with an acute exacerbation of chronic cholecystitis.

Medico-Legal

TEMPORARY MENTAL TREATMENT AND DIVORCE

The draftsmen of "Herbert's Act," which so radically altered the law of divorce, could not be expected to foresee all its practical implications. Divorce for insanity was a complete innovation, and on the whole the Act has worked well. One of the most striking gaps in it is, however, the absence of any mention of the "temporary" mental patient. The Act provides that a spouse may have a divorce if he/she can prove that the other party to the marriage is incurably insane and has been continuously under care and treatment for five years before the date of the petition. The patient is deemed to be "under care and treatment" in certain specific circumstances and no others: the words are satisfied if he/she is "detained in pursuance of any order or inquisition under the Lunacy and Mental Treatment Acts, 1890-1930," or under the statutes relating to mental patients in the fighting Services, or as a criminal lunatic. The words are also satisfied if, immediately after a period of such detention, the spouse becomes a voluntary patient and remains so for the rest of the five years, or again comes under detention. The object of this provision is obviously to avoid placing the voluntary status, created by the Mental Treatment Act, 1930, at a disadvantage by making it in any degree a bar to a divorce. Herbert's Act, however, does not say what happens if the patient has during the five years been a temporary patient under Sect. 5 of the 1930 Act.

A Case in Point

The question came before the President this summer¹ when a husband petitioned for a divorce and showed that his wife had been received into a mental hospital for temporary treatment in September, 1933; after the first statutory period of six months her treatment was duly extended for another three months by "directions" of the Board of Control—that is the word used in Sect. 5 of the 1930 Act. At the end of May, 1934, she was discharged relieved, and entered another mental hospital as a voluntary patient. She was still there at the date of the petition, and admittedly incurable. Voluntary treatment only counts for divorce if it follows a period of detention "in pursuance of any order." Was her temporary treatment detention of this kind? The President said that a "direction" is indistinguishable from an "order," and therefore her detention was in pursuance of an order under the 1930 Act. But she had had her temporary treatment extended; he declined to express an opinion on whether, if she had gone straight from her initial period of temporary treatment into voluntary treatment, the result would have been the same. When a temporary patient is received for treatment there is neither order nor direction, only an application and two medical certificates. The law may therefore conceivably be that the original period, unlike the extended period, is not "detention in pursuance of any order." That would be a ridiculous situation, and this point badly needs clearing up in an amending Act.

Desertion and Volition

In another divorce action² the question was whether temporary treatment interrupts a period of desertion. Herbert's Act makes desertion for three years a ground for divorce. By settled law, desertion must be wilful, intentional; and in a divorce appeal³ heard two years ago the Master of the Rolls held that if a deserting spouse is certified under the Lunacy Act, that is irrefutable evidence that he/she could no longer entertain the intention to desert, and the period of desertion was interrupted until the reception order was cancelled by discharge. (This is the only legal situation in which a certified patient is held to be irresponsible merely by reason of the certificate—an anomaly with no basis in reason.) A wife deserted her husband in 1937. Just two years later she was received into a mental hospital as a

temporary patient. A week afterwards she became a voluntary patient, and a month after that she was discharged. Mr. Justice Henn Collins was satisfied that she had deserted her husband for the required three years before the date of the petition, if the period of temporary treatment did not in law annul her *animus deserendi*—the wilful element in the desertion. At first sight there appeared to be a strong argument against the petitioner. To qualify for temporary treatment a patient must be incapable of expressing himself as willing or unwilling to receive such treatment—must, in the medical phrase, lose volition. If the wife had no volition concerning her treatment, she might conceivably have been inferred to have none concerning her desertion of her husband. The learned judge, however, declined to infer that in matters other than that of her treatment she had no will, and was incapable of forming an opinion or having an intention. Moreover, as she was not under certificate he felt himself entitled to consider medical evidence of her state of mind, and this testimony satisfied him that during the whole period of her treatment she was capable of forming an opinion that she did not want to go back to her husband. He added, referring to the decision in *Williams v. Williams*, that, untutored by higher authority, he should have said that once a spouse deserted the other, the desertion continued until the deserter did something positive to put an end to it, and that if any question arose, the burden of proving the end of desertion should fall upon the offending spouse, and should not be lifted merely because that spouse happened to become insane. In the light of the judgment of the Court of Appeal, however, he knew better, and he had only described his unenlightened state in order to say how indebted he was to the judges who had corrected him. On grounds of psychiatry and common sense, his former error seems far preferable to the enlightened view laid down by the Court of Appeal.

Universities and Colleges

UNIVERSITY OF LONDON

At a meeting of the Senate, held on October 29, the following resolution was unanimously adopted: "That the cordial thanks of the Senate be conveyed to Mr. H. L. Eason for his services to the University during his tenure of the office of Principal and, prior to that, as Vice-Chancellor, as Chairman of the Academic Council, the Finance Committee, and the Library Committee, together with an expression of their best wishes for his happiness in retirement." Mr. Eason retired from the office of Principal on September 30.

UNIVERSITY OF GLASGOW

At a graduation ceremony on October 18 the following medical degrees were conferred:

M.D.—C. H. Wilkie, †H. C. McLaren.
M.B., Ch.B.—J. S. Frew, †T. A. Berry, †N. C. Scott, †J. Gilchrist, †W. A. Macleure, †W. Barr, †A. W. McLeod, †W. B. Newton, †Agnes D. D. Murray, †J. Renwick, F. O. Adewole, A. B. Aiton, W. A. M. Akiyemi, J. M. Alexander, W. H. N. Angus, R. Auld, A. C. Barry, S. G. A. Bartlett, C. K. Boal, A. Bowman, R. D. C. Brackenridge, O. M. Brewster, C. H. Brown, Johanna J. S. Brunton, W. Burnett, W. F. Caldwell, Janet A. Christie, T. Cochrane, H. B. Cowan, G. McN. Cubie, J. T. Cunningham, P. N. Cunningham, T. McM. Curran, C. C. Cuthbert, Jean W. Cuthbert, J. K. M. Doss, W. A. Dewar, T. M. Donald, W. A. J. Donald, P. A. Duke, R. I. S. Dunn, R. L. Ewing, C. S. Farquharson, H. Ferguson, J. Frame, Marion K. Gilmour, B. Guyer, J. A. V. Hamilton, J. M. Hamilton, A. R. Harbison, J. Hemphill, Ruth L. Henderson, A. T. Hendry, M. J. Hood, J. Isaacs, J. Jacobs, Eileen I. Jamieson, J. S. Jeffery, G. Johnston, D. M. Kissen, N. McE. Lamont, W. H. Lang, W. R. C. Lang, I. Lumsden, Mary C. Lynas, R. McAndrew, W. F. McClement, A. F. McCoubrey, W. M. McDermid, A. MacDonald, J. McGloir, R. McIlwraith, Mary K. McKelvie, A. MacKinnon, H. A. Macleach, A. G. MacLeod, D. J. MacLeod, J. A. Macleod, N. F. Macleod, J. C. Meek, I. G. Meiklejohn, E. Millar, Kathleen M. Miller, W. I. J. C. Milligan, R. D. Muckart, J. Murphy, J. Newton, G. W. P. A. W. A. Parker, J. B. Pettigrew, R. E. Potts, A. R. Rennie, T. R. A. Richmond, D. Robertson, N. Sher, D. W. Short, A. M. Smeaton, A. B. C. Smith, J. F. Smith, F. M. Steel, Janet I. Stewart, Sylvia J. Strachan, T. Symington, A. C. Tait, G. R. Thomson, J. Urquhart, A. R. G. Watson, J. C. Wood, F. W. C. Yardwood, W. H. Yellowlees, Maïda B. Young, M. J. Young, Violet B. Young.

* With honours. † With commendation. ‡ In absentia.

James Shearer Frew gained (a) the Brunton Memorial Prize as the most distinguished graduate in medicine of the year.

¹ Benson v. Benson (1941), 2 All E.R., 335.

² Monckton v. Monckton (1941), 2 All E.R., 133.

³ Williams v. Williams (1939), P. 365.

1941; (b) the West of Scotland R.A.M.C. Memorial Prize as the candidate with the highest aggregate marks in surgery, medicine, and midwifery in the Final M.B., Ch.B. examinations held during 1941; (c) the Macewen Medal in Surgery as the candidate who obtained the highest aggregate marks in surgery in the Final M.B., Ch.B. examinations held during 1941; and (d) the Stockman Medal as the candidate who obtained the highest aggregate marks in the professional examinations in materia medica and therapeutics and medicine (written, oral, and clinical), excluding paediatrics, in 1941.

The John W. Weir Prize was awarded to William Alastair MacIure as the candidate who obtained the highest aggregate marks in midwifery and diseases of women in the final degree examinations in medicine held in 1941.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the Royal College of Physicians of London, held on October 30, with Sir Charles Wilson, President, in the chair, Sir Wilson Jameson, Dr. J. C. Spence, and Dr. W. A. Daley were elected Councillors. The following were re-elected representatives of the College: Sir Adolphe Abrahams on the committee of management of the Conjoint Board; Sir Comyns Berkeley on the council of the Central Midwives Board; Dr. John Hay on the court of governors of Liverpool University; and Sir Stanley Woodwork on the Central Council for District Nursing. Dr. C. Elgood was elected a member of the Library Committee.

The President announced that he had invited Sir Wilson Jameson to give the Harveian Oration and Surgeon Captain Macdonald Critchley to give the Bradshaw Lecture, both in 1942; that the College had awarded Linacre Scholarships at the King's School, Canterbury, to T. Stapleton and D. M. D. Evans; and that the Jenks Scholarship had been awarded to T. R. L. Finnegan, late of Epsom College.

The following, having satisfied the Censors' Board, were elected Members:

Margaret D. Baber, M.D.Lond., W.-W. Brigden, M.B.Camb., H. A. Burt, M.B.Camb., D. L. Caldwell, M.B.Camb., G. W. M. Findlay, M.D.Ed., G. M. Fitzgerald, M.B., G. Flavell, F.R.C.S., G. S. Graveson, M.B., Ursula James, M.B.Lond., J. Marks, M.D.Lond., T. Parkinson, M.D.Lond., F. T. G. Prunty, M.B.Camb., I. B. Sneddon, M.B., Surg. Lieut. R.N.V.R.

Licences

Licences to practise were conferred upon the following 159 candidates (including twenty-one women) who have passed the final examination of the Conjoint Board and have complied with the necessary by-laws:

H. Anderson, R. H. Andrews, I. J. Anrep, C. D. Baker, H. Barrada, E. Barry-Smith, A. W. Bauer, P. Baxter, H. Beck, M. Bednar, C. J. A. Bell, J. A. R. Bickford, Margaret A. Billingham, D. A. Blacketer-Simmonds, J. Borrowdale, D. S. Boyle, S. V. Brookes, Jean L. Broughton, R. J. D. Browne, C. J. Bruhn, J. D. Bruzard, Olive N. Bywaters, D. A. K. Carnegie, D. W. F. Charlton, W. H. Chase, J. P. Childs, N. F. Clarke, B. U. Coffey, H. I. Coombs, R. A. Craig, A. F. Crick, M. C. Cross, F.-X. Darné, R. G. Dewhurst, L. W. D. Drabble, F. M. P. Eckstein, J. R. Ellis, Shifra Ernst, A. T. G. Evans, A. J. Evans, E. J. S. Evans, J. W. G. Evans, J. H. W. Fagan, T. N. Fison, J. M. Fitton, A. W. H. Foxell, Beryl M. Givan, E. C. E. Golden, Gertrude Goldscheider, J. G. Goodhart, A. J. R. Gottfried, J. D. C. Gowans, K. G. Green, B. P. Griffin, H. J. Hagger, C. L. Hall, Doris N. Hall, Constance M. Hallett, J. H. G. Halliday, Penelope K. Hammick, B. E. F. Hammond, P. A. S. Hargrove, C. Harris, R. J. Harvey, T. Haw, Ursula M. Hickman, A. W. Hind, S. J. Hinds, W. K. G. H. L. Hoffmann, A. E. Howarth, D. R. Hughes, Isabella C. F. Hungerford, M. Ich, E. B. Jarrett, R. Jenkins, C. H. Jones, D. G. Jones, K. C. D. Jones, S. Jung, F. L. King-Lewis, F. M. Lancaster, R. Leigh, K. H. Lim, Wai Kwan Lim, J. Lomas, J. D. B. Longley, Helen C. Longmore, M. Lustigman, O. Lustmann, P. M. McAllen, H. McColl, G. Machanik, L. R. McLaren, T. M. M. McLean, H. L. Mcullen, G. Macvicar, Mary B. Maish, Betty M. Margetts, G. Mariani, H. E. S. Marshall, S. M. Ma'tuk, C. H. Merry, J. E. Moore, J. E. E. Morgan, P. J. L. Mumford, J. W. Nelson, R. J. Newman, G. D. R. Patten, Jean W. Paul, A. Pearce, B. O. Pepper, R. K. Phillips, W. A. Porter, Elvira Power, T. M. Prichard, J. P. Quailan, J. F. P. Quinton, R. J. W. Rees, Edith Rhodes, J. W. F. Richardson, H. A. Ripman, J. T. Robinson, W. G. Roper, I. Rosen, C. F. Ross, R. K. Ross, H. Rotenstein, D. T. Rowlands, D. K. Sambrook, W. Schiller, G. C. Schwizer, H. P. Scurlock, C. F. Scurr, A. G. Seaman, J. P. Sharp, A. L. H. Smith, B. J. Smith, A. M. Stevenson, M. Szinay, J. H. Tasker, H. D. Teare, D. I. Thomas, R. D. St. G. Tucker, K. O. A. Vickery, D. G. Villiamy, E. Vire, G. H. Waddington, Glenys J. Wade, Vera B. Walker, G. G. Wallis, D. P. Walther, C. W. Walton, G. N. Weber, Joan M. Whiteman, D. Williams, E. J. Williams, M. H. C. Williams, D. H. Wright, E. J. Young-Thompson.

Diplomas

Diplomas in Child Health were conferred, conjointly with the Royal College of Surgeons of England, upon the eleven candidates whose names were printed in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of October 25 (p. 597). Diplomas in Public Health were conferred, jointly with the Royal College of Surgeons of England, on L. C. Lodha, L. G. Norman, and M. A. G. Ward.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a quarterly meeting of the council, held on October 25, with the President, Prof. W. Fletcher Shaw, in the chair, changes in the regulations for the Membership, to take effect in January, 1943, were approved.

The following were admitted to the Membership of the College:

G. Boyd, Glasgow, E. Gledhill, Batley, R. MacI. Millen, London, Constance E. Peaker, Leeds, Kathleen M. Robinson, London, Katherine C. Rogers, London, R. X. Sands, London, Violet E. A. Sykes, London, G. Wynn-Williams, London.

The following have satisfied the examiners for the Diploma of the College:

Elizabeth C. W. Barker, London, Constance L. Beynon, Brighton, L. A. Crutenden, Ripley, Dorothy Cunningham, Preston, R. C. Dennis, R.A.F.V.R., A. A. Fyfe, London, R. P. Gamble, Bishop's Stortford, Jean L. Hallum, Birmingham, L. W. Hefferman, Swansea, G. Hollingsworth, Macclesfield, Hilda E. McNamara, Canada, P. S. Norris, Pembury, Jean F. Thompson, Leeds, H. B. Watson, Birmingham, Eva M. M. Willett, Southampton, H. G. Wolskel, London.

Following the meeting the William Blair-Bell Memorial Lecture was given by Mr. W. C. W. Nixon on "Diet in Pregnancy."

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the final examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.G.:

C. E. V. P. Amerasinghe, B. Beck, G. C. Cope, T. V. Darke, T. Dean, A. M. A. El Far, Y. Farooq, R. Friedman, A. R. Gemmell, M. F. El Gizini, D. F. P. Gordon, D. Granet, B. Greenberg, J. H. Haldane, Margaret M. Hanretty, N. Hornstein, Dorothy L. D. Johnston, G. Johnstone, H. E. Klein, R. I. Kynaston, Henrietta Lennon, J. K. Lotinga, B. H. Lunine, H. Macpherson, O. P. Markandya, H. J. F. Mitchell, E. K. Neidich, J. O'Hara, V. Poonosamy, E. H. Reinsberg, C. B. Robinsen, J. Schneiderman, R. Smith, T. Tuller.

The following graduates of recognized foreign universities were also admitted licentiates: S. Riterband, Else Wolfsohn.

The Services

CASUALTIES IN THE MEDICAL SERVICES

ROYAL NAVY

The name of Temporary Surgeon Lieut. ROBERT TAYLOR, R.N.V.R., is included as "Missing, Presumed Killed" in an Admiralty Casualty List published on October 25. He was educated at the University of Glasgow, where he graduated M.B., Ch.B. in 1940. He joined the British Medical Association soon after qualification.

ROYAL ARMY MEDICAL CORPS

Prisoner of War

War Substantive Captain John Burrows Sherman.

DEATHS IN THE SERVICES

Major ARTHUR BRODIE HAMILTON BRIDGES, O.B.E., R.A.M.C. (ret.), died at Cheltenham on October 22, after an operation, aged 54. He was born on November 2, 1886, received his medical education at St. Thomas's Hospital, and took the M.R.C.S., L.R.C.P. in 1912. Entering the R.A.M.C. as lieutenant, from the Special Reserve, in 1913, he became captain in 1915, and retired as major in 1933. While on the Reserve of Officers he was employed for a time in London, and was recently residing at Kilmington, Devon. He served during the war of 1914-18, was mentioned in dispatches in 1916, and received the O.B.E.

Medical Notes in Parliament

The General Medical Council (Temporary Provisions) Order, 1941, which extends until December 31, 1942, the term of office of certain direct representatives, was laid before both Houses of Parliament on October 16.

Feeding the Children in Wartime

In the House of Lords on October 21 Lord WOOLTON outlined the general policy of the Government on the whole field of nutrition in so far as it was associated with food. Lord Woolton also referred to Mr. Butler's announcement that day in the House of Commons. He said that we were all now living on a diet mainly influenced by the extent of the domestic ration. This ration was based on the average need of the average family; it was not designed to meet the needs of special classes of the community, and there was a danger that those who required special consideration in the matter of their diet, either for the growth of their bodies or the maintenance of more than average physical strength, might find this diet insufficient. This was particularly the case with children, who needed more than average supplies of the body-building foods.

At present there were 5,000,000 children in the elementary and secondary schools, and only 300,000 of them were receiving meals in school. Small as this number was, it represented 100% increase during the past year. The provision of school meals was also extremely uneven in the country: whereas in a few areas as many as 30% of the children were having meals in school, in others there was little or no provision for them. Financial considerations alone had not impeded the development of the feeding of school children. There had been other factors. There was, of course, the question of getting supplies of food. They could now assure local education authorities that a sufficiency of food would be forthcoming, and they had arranged for priority supplies to enable school canteens to serve balanced meals of the type which the medical and scientific advisers of both the Board of Education and the Ministry of Food considered necessary for securing the growth and maintaining the health of school children. These provisions would apply to all schools.

EMERGENCY FEEDING CENTRES TO BE USED

The Ministry of Food had made emergency arrangements for feeding the people in the event of war conditions making it necessary for there to be a great extension of communal feeding: 170 cooking depots had been set up by local authorities, under the auspices of the Ministry of Food; that number would presently be increased to 250. The depots had already a capacity for providing 300,000 meals a day for school children, and this number would be increased to 400,000 meals. These depots would now be used daily for the children of the nation. There were also other wartime cooking facilities, but local authorities would find it necessary to start new individual or central kitchens. These kitchens would be equipped from a central pool of equipment organized by the Ministry of Food, which was already stocked with many of the necessary items and which would be extended to include articles specially suitable for school purposes.

MILK SUPPLIES

Feeding children in schools, he continued, was but one aspect of the problem of maintaining the nutritional life of the country. They could, by adopting an informed and sensible control of the things that we imported and by continuing to benefit by the great effort the farmers were making to grow the food needed, secure that in spite of a restricted diet there should be no deterioration in the standard of health of the nation and no failure of output through shortages of food. The provision of plentiful supplies of milk for nursing mothers and for children under 5 was a plan that was already working. The Government had recently taken some additional control over the milk supplies. The main purpose had been to ensure that growing children, up to and including 17, should have

adequate milk, both at home and at school. That plan was at the present making no call on the forbearance of the country, but as winter proceeded and liquid milk supplies became less it might call for sacrifice on the part of those who were older and who, save in exceptional circumstances for which he had provided, could quite well do with less liquid milk. They had also arranged that such oranges as they were able to bring into the country should be sold in the first instance to children, and on a ration: but recognizing that it was inevitable that there would be a shortage of fruit they had taken special steps to secure fruit juices for distribution to children to make up any deficiency in their diet which, in the ordinary course of events, would be supplied by fruits in their natural state.

The principle that they were adopting to secure the health of children was to see that they should be fed where they were congregated. They had adopted the same policy with industrial workers. They needed widely different foods. Heavy workers needed more meat or cheese or fish than the office worker; in some forms of work more sugar was required than in others. They therefore proposed to allocate foods to industrial canteens and catering establishments according to a broad general classification of their needs. They would divide them into three groups, according as they catered for the heavy worker, the medium-heavy worker, and the sedentary workers or those engaged in light occupations, and provide food accordingly. In the case of miners they would before the end of this year cater in some measure for 85% of the mining population by having a supplementary ration served at the pit-head before the men went down the pit.

MEDICAL APPROVAL

Lord HORDER welcomed Lord Woolton's statement. He said that although so far no overt signs of malnutrition were to be observed, if we waited until those signs did appear we should wait too long. They would mean that grievous injury had been done which would leave a permanent scar for the rest of life. So far we had been fortunate. The Government evacuation scheme had undoubtedly acted as a deterrent against deficiency diseases of children. We did not know at present how far our children might be from a state of malnutrition; modern science gave us no means of measuring the safety of that margin, and for that reason he emphasized the time factor. The child was at the mercy of chance in any rationing scheme, and with most mothers knowledge marched a good way behind affection. That fact was one reason why family allowances, excellent in themselves, could not be expected to preserve the child against malnutrition nor to solve this problem of safeguards. The school was the only place where defects might be made good and hazards warded off. It was gratifying, therefore, that the Government had accepted that principle in full.

It was good to hear that Lord Woolton could see his way to supply the protective and body-forming foods necessary in preparing the diet of a child and to provide the requisite equipment, or a considerable amount of it, and that the local authorities were assured of a Treasury grant of such generous dimensions. Experience showed, however, that quite frequently and for a long time there was a lag at the periphery, even when direction had been given and action taken at the centre, otherwise one could feel quite optimistic about protecting the health of the children. He was not pessimistic, however, and he felt that this was a red-letter day in the annals of our children's nutrition. He did not doubt that the necessary encouragement and stimulation from the President of the Board of Education would be forthcoming, which would be necessary for the local education authorities, the teachers, and the parents to get the machinery going as soon as possible.

Lord ADDISON expressed satisfaction with Lord Woolton's statement. He was, however, very apprehensive about what was going to happen to the milk supply, and he hoped Lord Woolton would waste no time in considering that question.

INCREASED EXCHEQUER GRANTS

On the same day Mr. BUTLER, replying in the House of Commons to Mr. Lees-Smith, made a statement on the development of the school meals and milk services, with a view to ensuring the proper nutrition of children. He said that at

active campaign for the expansion of the provision of meals for school children had been conducted by his Department during the past year, and had resulted in doubling the number of children receiving midday meals daily. In consultation with the Minister of Food they had now decided on certain important measures which he hoped would secure an immediate and large development of this service. He had accordingly obtained the Chancellor of the Exchequer's approval to an increase of 10% in the rate of grant on authorities' expenditure on provision of meals, subject to an overriding maximum grant of 95%. He was further raising the minimum rate of grant from 50% to 70%. These steps would go far to remove any financial obstacle to expansion and would, he hoped, lead to a great increase and levelling-up of provision in all areas. The Minister of Food was also placing at the disposal of the local education authorities the facilities provided by the chain of cooking depots which were being set up near the large centres of population. Authorities would now be able to obtain from the depots substantial meals, which would be delivered to schools or school canteens in the neighbourhood in large and increasing numbers. He aimed at securing an increase in the proportion of children receiving milk under the Milk in Schools Scheme from some 60%, where it now stands, to as near 100% as possible. To this end it had been decided that the whole of the cost of the provision of free milk to necessitous children and of the handling of the milk in the schools should be reimbursed by the Exchequer.

Committees on Nurses' Salaries

Mr. ERNEST BROWN, answering Miss Lloyd George on October 16, said he had appointed Lord Ruchcliff chairman of the committee which he had set up for the purpose of drawing up as soon as possible agreed scales of salaries and emoluments for State-registered nurses employed in England and Wales in hospitals and in the public health services, including the service of district nursing, and for student nurses in hospitals approved as training schools by the General Nursing Council for England and Wales. The committee would consist of two panels, one representing employers and the other employees. He hoped to announce the names in about a fortnight. Some nurses were already covered by agreements made through the National Joint Council for Local Authorities. It would not be appropriate to refer to the committee the salaries of nurses employed in industry.

Asked by Mrs. Hardie about the appointment of a Scottish committee on nurses' salaries, Mr. TOM JOHNSTON said he had appointed Lord Craigville to be chairman of a similar committee for Scotland.

Tuberculosis: Increase in Scotland

On October 21 Mrs. HARDIE asked the Secretary of State for Scotland in what districts in Scotland the increase in notified cases of tuberculosis had taken place. Mr. JOHNSTON, in reply, circulated the following table:

Region	1938			1939			1940			41 weeks to October 11, 1941		
	Pul-mon-ary	Non-pul-mon-ary	Total	Pul-mon-ary	Non-pul-mon-ary	Total	Pul-mon-ary	Non-pul-mon-ary	Total	Pul-mon-ary	Non-pul-mon-ary	Total
Northern Area	149	124	273	174	100	274	165	88	253	129	79	208
North-Eastern Area	238	251	489	248	239	487	283	238	521	231	198	429
South-Eastern Area	495	386	884	449	342	791	531	318	849	442	264	706
Western Area	674	397	1,071	591	309	900	681	366	1,047	564	308	872
Total	3,234	1,614	4,848	3,195	1,450	4,645	3,540	1,494	5,034	3,182	1,139	4,321
Total	4,793	2,772	7,565	4,657	2,440	7,097	5,200	2,504	7,704	4,548	1,988	6,536

Mrs. Hardie pointed out that the rate had gone up in Glasgow by 20%, and that the increase had been mainly among the young working population. She asked if the Minister did not think that steps ought to be taken to look into the causes

with a view to remedying them, particularly as the figures were still rising.

Mr. JOHNSTON said that they were taking what steps were available, although they were very limited, to examine this matter. The Medical Research Council had had their attention drawn to it. Replying to Mr. Kirkwood, Mr. Johnston said he thought that housing, evacuation, blackout difficulties, war strain, and a number of other causes had contributed to the increase in tuberculosis since the war began. Asked by Dr. Summerskill why, if his reasons were right, the increase should be larger among women, Mr. Johnston said it was possible that the strain of war conditions was greater among them than among men.

School Meals Service for Scottish Children

Mr. JOHNSTON on October 21 informed Mr. G. A. Morrison that he hoped to secure an immediate and substantial development of the schedule meals service in Scotland by arranging for advantage to be taken of facilities provided by the Minister of Food, and, where these were not available, by encouraging education authorities to make their own provision. Scots law at present permitted food to be provided for necessitous children only when the individual child was unable, by reason of lack of food, to take full advantage of the education provided. But malnutrition should be prevented, and a short Bill, designed to give education authorities power to supply food free of charge to necessitous cases without waiting for evidence of malnutrition, would be introduced in the near future.

Registrar-General's Reports

Miss HORSBROUGH told Sir Ernest Graham-Little on October 22 that publication of the Registrar-General's Reports was not discontinued, though wartime conditions had delayed the completion of the report for 1939. It had been decided to print in the first instance a limited edition of this volume, which would be held by the Registrar-General and made available for consultation and study by Government Departments and other bodies or persons having an acknowledged interest in its contents. The interests of medical research would receive sympathetic treatment under this arrangement.

Care of Child Air-raid Casualties

Mr. ANDERSON asked on October 23 what provision had been made for treatment needed by children injured by enemy action. Mr. Brown said children injured by enemy action and needing treatment in hospital were admitted to hospitals in the Emergency Hospital Scheme and provided with all requisite medical attention and care without charge, including, where necessary, the facilities afforded by the specialized treatment centres and the fracture organization. After discharge from hospital any necessary out-patient and domiciliary treatment was given. Amputation cases were referred to the Ministry of Pensions' limb-fitting organization, where suitable artificial limbs were provided and the child was trained in their use. On discharging child casualties, hospitals notified the Board of Education; the local education officers could thus be informed of the arrival of the child in their area, so that any special arrangements for teaching could be made.

Increase in Infant Mortality in Scotland

On October 26 Mr. JOHNSTON told Mrs. Hardie that the latest figures of infantile mortality in Scotland available were those for the first six months of this year. Comparing these rates with the average of the rates for the first six months of 1937, 1938, and 1939, the burghs showing the largest percentage increases were Dumbarton, Rutherglen, Hamilton, and Paisley. Considerable increases were found in the counties of Nairn and Sutherland, but the small number of births in the first six months of 1941 rendered any comparison unreliable.

Answering supplementary questions, Mr. JOHNSTON said that the Department was investigating the causes of infant mortality and endeavouring to prevent it. The increase of infantile mortality arose from a very large number of causes, all directly attributable to war conditions.

Edible Protein from Grass.—Answering Dr. Edith Summerskill on October 15, Major LLOYD GEORGE said research was proceeding on the production of edible protein from young grass. A greyish material looking like cheese had been produced on a purely experimental scale. Considerable technical difficulties must be overcome before large-scale production could be contemplated.

Medical Examination of Evacuated Children.—Mr. MESSER asked on October 16 whether there was a routine medical examination of all evacuated school children. Mr. R. A. BUTLER said routine medical inspection was being carried out in virtually all reception areas. All evacuated children who fell within the prescribed age groups were examined. In one or two areas a modified scheme of inspection had been adopted on the lines suggested in the Board's Circular 1523. The Board laid it down that the facilities provided for medical treatment of local school children in these areas should be equally available for evacuated children.

Return to Work of Unfit Miners.—Mr. RHYS DAVIES asserted on October 16 that ex-miners who had left the pits on medical advice were now directed by the Ministry of Labour to return to work underground against the advice of their own doctors. He further said that the medical officers of the Ministry often passed such men as fit for pit work, although when they reached the pithead the doctor employed by the colliery company declared them medically unfit. Mr. BEVIN refused to accept the suggestion that men were often wrongly certified fit for coal-mining work. In cases of doubt the practice was to call for independent medical evidence.

Death Rate in Wales among Young Women.—On October 21 Miss HORSBROUGH, replying to Mr. J. Griffiths, said that the death rates per 1,000,000 female population in Wales between 15 and 25 were as follows: 1935, 1,749; 1936, 1,737; 1937, 1,566; 1938, 1,423; 1939, 1,454. Figures were not prepared for the separate age groups 15 to 20 and 20 to 25; the corresponding 1940 record was not yet available.

Women Medical Students at London Hospitals.—Miss CAZALET on October 23 asked Mr. Brown, when drawing up his scheme for re-organization of hospital services, to consider the admission of women as medical students to those London voluntary hospitals which did not now accept them. Mr. Brown said the point would no doubt be taken into consideration.

Notes in Brief

Twenty-two county councils in England and Wales have appropriated the whole or part of Public Assistance Institutions for public hospital purposes.

In England and Wales there were no deaths of children under 5 attributable to small-pox in 1938, 1939, and 1940. Deaths of children under 5 assigned to vaccination numbered 5 in 1938, 1 in 1939, and 6 in 1940. This classification does not rule out the probability that such deaths had other contributory causes.

Since the outbreak of war 141 officers and airmen have been invalidated out of the Royal Air Force for defective hearing. From the Navy between September 1, 1939, and March 31, 1941, 287 men were invalidated out for the same cause. Similar information for the Army is not available.

A general issue of anti-catarth vaccine is not made in the Royal Air Force, but supplies are available in all cases where medical officers consider this treatment desirable.

Major Lloyd George told Prof. A. V. Hill on October 8 that the question of adding calcium to food, in view of its deficiency in the national diet, was still under consideration by the Ministry of Food. He added that the use of flour of 85% extraction was in accord with the advice given by the Scientific Committee on Food Policy.

Medical News

A Chadwick Public Lecture on "Hygiene Technique in Building, or the Economic, Psychological, and Health Aspects of Surface Treatment" will be given by Mr. F. R. Horns, F.R.I.B.A., at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, on Tuesday next, November 11, at 2.30 p.m.

The British Institute of Philosophy announces a lecture entitled "The Universe in Relation to Modern Physics," to be given by Prof. Herbert Dingle at University Hall, 14, Gordon Square, W.C.1, on Friday, November 14, at 3 p.m. Cards of admission can be obtained on application to the Director of Studies at University Hall.

Colonel Hugh Cairns will deliver a lecture on "Head Injuries" at the Weston Hotel, Bath, on Thursday, November 13, at 5.30 p.m. All Service medical officers and civilian practitioners will be welcome.

Prof. J. C. Drummond, D.Sc., Scientific Adviser to the Ministry of Food, will deliver a series of lectures on "Recent Advances in the Science of Nutrition and their Significance in Wartime" at the Royal Institution, 21, Albemarle Street, W. on Tuesdays, November 25 and December 2, 9, and 16, 2.30 p.m.

A meeting of the North-Western Tuberculosis Society will be held at the Tuberculosis Offices, 352, Oxford Road, Manchester on Thursday, November 13, at 3 p.m., when the president Dr. G. H. Leigh, will speak on "Facts and Fancies in the Tuberculosis Death Rate." The honorary secretary, Dr. J. Fleming (11, Woodvale Road, Knutsford), reminds members of the Tuberculosis Association that they are cordially invited to the society's meetings.

The Czechoslovak Medical Association in Great Britain is holding a reception for English doctors, under the auspices of the Czechoslovak Institute in London, on the afternoon of November 11, at 18, Grosvenor Place, S.W.1.

At the annual general meeting of the Association of Anaesthetists of Great Britain and Ireland held on October 28 the following officers were elected for the coming year: President, Lieut.-Colonel Ashley Daly, R.A.M.C.; vice-president, Dr. C. F. Hadfield; treasurer, Dr. Z. Mennell; secretary, Dr. A. D. Marston.

Dr. F. W. Routley, National Commissioner of the Canadian Red Cross, announces that it has been arranged to dispatch to the Russian Red Cross as quickly as possible 100,000 dollars' worth of special medical supplies.

A pamphlet has been issued by the Ministry of Home Security giving guidance to all holders of radium on the precautions which should be taken to prevent dispersal of radium through enemy action. Sketches are reproduced showing the approved type of bore-hole and of steel container. Medical officers of health are asked to take all practicable steps to ensure that the necessary precautions are carried out. A copy of the pamphlet may be obtained on application to the Publications Branch, Ministry of Home Security, Horseferry House, S.W.1.

The National Baby Welfare Council has obtained information from evacuation areas throughout the country as to the number of children under 5 years of age still remaining in such areas. It has been ascertained that the figure exceeds half a million. The Council has called the attention of the Ministry of Health to this fact and has requested that evacuation should be made possible to all children under 5 years of age whose parents are desirous of sending them to safer areas.

The July issue of the *South African Medical Journal* contains a quarterly scientific number, including articles on endemic fluorosis in the Pretoria district, climatic strain in malaria, and antigenic qualities of certain strains of avirulent *B. pestis*.

Dr. Luzius Ruedi has succeeded Prof. Ulrich as director of the ear, nose, and throat clinic at Zurich.

Dr. Roderick MacLeod, past chairman of the Sunderland Division, B.M.A., has retired from the post of medical officer of health to Hetton District Council after twenty-five years' service, and has been given a Sheraton writing desk subscribed for by councillors and officials. In making the presentation the chairman of the Council said that Dr. MacLeod had devoted his time and talents without fear to the betterment of the people's health. Dr. MacLeod has also been head of the casualty service in the Hetton district, and he and Mrs. MacLeod recently received a plated entrée dish, suitably inscribed, as a gift from the casualty service personnel.

No. 42

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 18.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) Scotland, (c) Eire, (d) Northern Ireland. *Deaths recorded under each infectious disease, in England and Wales (including London).* (e) The 16 principal towns in Scotland, (f) The 13 principal towns in Eire, (g) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1941					1940 (Corresponding Week)

* Except for Northern Ireland, typhoid and paratyphoid are now notified separately.
† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.
‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

The number of notifications of infectious diseases in England and Wales was smaller than in the preceding week. The only exceptions were whooping-cough, with an increase of 9 cases, and poliomyelitis, with a relatively large increase of 12. Scarlet fever and dysentery, with a decrease of 141 and 64 cases respectively, were the only infectious diseases that showed a large deviation from the numbers recorded in the previous week. The incidence of infectious diseases in Scotland was smaller than in the preceding week: scarlet fever, measles, and whooping-cough declined, but there was a small increase of 9 cases of diphtheria, and the number of notifications of cerebrospinal fever was 1 in excess of last week's total.

Poliomyelitis

Fifty cases of poliomyelitis were notified in England and Wales during the week, this being the largest weekly total recorded during the year. The rise was the result of a recurrence of cases in Berkshire (3), Buckinghamshire (3), and Oxfordshire (4), after an interval of one week without any cases, and a rise in the notifications, from 2 to 8, in Surrey. Multiple cases were notified in the administrative areas of Berkshire (New Windsor M.B., 2); Oxfordshire (Oxford C.B., 3); Suffolk West (Bury St. Edmunds M.B., 2); Surrey (Croydon C.B., 2; Godalming C.B., 2); Sussex, East (Brighton C.B., 2).

Dysentery

The notifications of dysentery in England and Wales showed a reduction of 64 cases compared with last week as a result of the decline in the outbreaks in Kent and Somersetshire, where only 4 cases and 1 case respectively were notified, compared with 64 and 18 in the preceding week. Twelve cases, an increase of 6, were returned from Northamptonshire (Northampton R.D.), and 11 cases, an increase of 8, from Epsom and Ewell M.B. (Surrey). A further 21 cases were notified during the week in Bristol C.B. Nine administrative areas contributed to the 26 cases returned from Lancashire.

The notifications in Scotland were 7 fewer than in the preceding week, and, of the 93 cases notified, 35 were reported in Lanark County. The number of notifications increased in Edinburgh, from 10 to 18, and decreased in Glasgow, from 21 to 9, and in Dundee, from 14 to 11.

Scabies

The reports of local medical officers show that scabies is still very prevalent. Although no comparative figures are available it seems that the incidence of this complaint has increased considerably since the war started. It had been steadily increasing in the immediate pre-war years, and the large number of infected persons in some areas is a matter of concern to the local authorities.

Week Ending October 25

The number of cases of infectious diseases notified during the week in England and Wales included scarlet fever 1,224, whooping-cough 1,985, diphtheria 1,017, measles 745, cerebrospinal fever 88, poliomyelitis 50, dysentery 139, paratyphoid 53, and typhoid 23. Fifteen deaths were attributed to influenza.

L. Pelner (*Amer. J. Dis. Child.*, 1941, 62, 358), who records two personal cases, illustrates the rarity of relapses in measles by the fact that Rolleston and Ronaldson noted only nine examples among 11,749 cases of measles, and claimed that in several cases of so-called relapse the prodromal rash had been mistaken for the primary attack. In Pelner's first case, which was that of a boy aged 8, the first attack occurred at the age of 26 months and the second at 8 years. Severe abdominal pain occurred in both attacks. In the second case, which was in a girl aged 9 years, the first attack had appeared at the age of 6 years. Both attacks were mild.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE No.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent*, London; SECRETARY, *Medisecra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Vocal Resonance and Fremitus

Dr. MARY D. SHERIDAN (Manchester) writes: Will any physiologist be kind enough to explain to me the exact physical explanation of vocal resonance and vocal fremitus? Neither of them, of course, occurs with voiceless consonants, so that they must both have something to do with the vibration of the vocal cords during phonation, but I should be grateful to have a more exact explanation.

Income Tax

Income Arising Abroad

R. S. has recently acquired an income in one of the Dominions which he had not intended to transfer to this country during the war. He is, however, informed that the income is chargeable here whether it is remitted or not.

* That is correct—assuming that the income does not arise from a trade, etc., or employment carried on by our correspondent. We understand, however, that in present circumstances the Revenue authorities are willing to leave the amount of tax involved in abeyance unless and until the income is remitted. We suggest that if practicable R. S. should call and explain the matter to the inspector concerned.

E.M.S.: Billeting Allowance

A. H. inquires whether billeting allowances received in cash are assessable.

* This would seem to be the case, unless the particular circumstances are such as to show that the amounts received are in the nature of travelling or subsistence allowances. The argument in favour of the second alternative would be strengthened if in the particular case the place of employment were subject to fairly frequent change.

Division of Partnership Liability

A. M. inquires as to the method of adjustment, as between two partners, of the amount of tax charged upon the firm.

* The firm as such is legally liable to the Revenue for payment of the tax. But the basis of division of profits is usually incorrect as applied to the sharing of the tax charged (e.g., one partner may be married and the other single), and it is customary for the individual shares of each partner to be agreed with the inspector of taxes and for the partners to pay their respective shares into the firm's bank account.

Local War Committee Bureau

H. B. inquires whether the authorities can require a bureau to supply a statement of the payments made to individual practitioners—both private and insurance fees are involved.

* We do not see on what legal grounds such a statement could be compelled, seeing that the practitioners are not in the employment of the bureau and that the sums passed on are gross receipts rather than "income." We suggest that if the authorities ask for a statement they should be requested to quote the legal authority for their demand.

Life Assurance Relief—Restriction

"K.L.B." wishes to take advantage of Section 4 of the Finance Act for 1941, providing that the "total income" by which the one-sixth restriction of the allowance can be measured may be related

to the year 1938-9. Does that mean the actual income for 1938 or the amount assessable for that year—on the basis, as regards salary, of the actual amount for 1937-8?

* The effect of the section as modifying the main provision—Section 32 (3) (a) of the Income Tax Act, 1918—is that the one-sixth may be applied to the total income for the year 1938-9 from all sources "estimated in accordance with the provisions of the Income Tax Acts." The result is that so far as income from salary is concerned the amount affected is the salary for 1937-8, as that income must be "estimated in accordance with the provisions of the Income Tax Acts" for 1938-9 on the previous year's basis.

Honorarium from Hospital

"A."s income is derived partly from salary, assessed under Schedule E, and partly from private practice, assessed under Schedule D. He also has an honorarium of £100 per annum from a hospital. Under which schedule is the honorarium assessable?

* Under Schedule E. There is, however, a practice of hon standing under which such honoraria are included with the general practice receipts if that is more convenient and does not materially affect the amount of tax payable—as it would, for instance, if the appointment were a new one.

LETTERS, NOTES, ETC.

Hot Drinks for Trapped People

Dr. MAURICE E. J. PACKER, M.O. in charge of No. 1 Mobile Unit, Bristol, writes: Our experience of air raids has shown us the need for some apparatus that will enable us to give hot stimulating drinks to patients (shocked or otherwise) who are entrapped. My original suggestion was some rubber tubing attached to a feeding cup, but Sister Vetlesen has made the great improvement shown in the diagram. As so many Morrison shelters are now in use, the scope for such apparatus this winter will be greater than ever.

District Nurse for Home Guard Casualties

The Editor of the *Nursing Mirror* writes: Most writers are agreed that the present medical and surgical provision for Home Guard casualties is insufficient, and that casualties are most likely to occur in isolated country districts where there are few facilities for coping with them. It is being wisely suggested that local Home Guard medical officers should make urgent and speedy effort to remedy this, and equip casualty collecting posts where such is needed. May we suggest that they will find most competent assistants in the local district nurses—women who, by training and experience, are equipped to cope with any emergency, to assume responsibility in the absence of a doctor, and to improvise with orthodox material and methods are not available. The district nurse knows the neighbourhood, the buildings, the people. She can advise on choice of post, and organize her own local team of helpers. Most important of all, she can be left under instruction to deal with the casualties while the sorely pressed M.O. goes to other places urgently needing him. The doctor could have a more reliable deputy.

Cigarette Smoking and Tachycardia

Dr. F. GORDON CAWSTON (Durban) writes: Tachycardia in the Tropics is frequently associated with bowel infection or poor absorption, for which small and repeated doses of an antidiarrhoeic are to be preferred to active purgation; but the report by Claude Fothergill (December 23, 1939, p. 1253) that a diminution of cigarette smoking assists in bringing the pulse back to normal in soldiers convalescing from enteric fever, deserves careful consideration in view of the large quantity of cigarettes contained in comforts for the troops and the possible absence of poisonous constituents other than nicotine.

A Newspaper's Inquiry

Dr. H. SUGARÉ (Leeds) writes in reply to Dr. E. Starling, who was asked by a local newspaper to confirm the birth of a child (October 18, p. 568): This inquiry is done probably in order to prevent the possibility of a hoax. On the birth of our child eighteen months ago I phoned the local evening paper to announce the event. This was only accepted after I had in turn phoned my number—to confirm, no doubt, that Dr. S. was speaking. The explanation given me of the procedure was as mentioned above.

HEMIPROSTATECTOMY FOR UNILATERAL ADENOMATOUS ENLARGEMENT

BY

W. SAMPSON HANDLEY, M.S., F.R.C.S., Hon. F.A.C.S.

Consulting Surgeon to the Middlesex Hospital

This paper deals exclusively with cases in which obstruction to urination is due to adenomatous enlargement of one lateral lobe of the prostate, while the other remains of normal size. It includes in its survey those numerous cases in which, though no increase of either lateral lobe is appreciable on rectal examination, cystoscopy reveals a middle lobe pushed up behind the urethral outlet by incipient enlargement of one or other lateral lobe. Pure middle-lobe obstructions nearly always belong to the class of unilateral enlargements.

In 1895, at a time when suprapubic operations for enlarged prostate were usually restricted to the removal of the vesical projection, and when consequent failure to relieve obstruction was erroneously attributed to atony of the bladder, Eugene Fuller of New York maintained: "If, however, all the hypertrophies, median, lateral, and round about the prostatic urethra, are removed . . . the results, as far as the bladder is concerned, are, barring mortality, satisfactory." Thomson-Walker in 1930 commented on this statement: "Here for the first time was laid down that the routine operation of prostatectomy must include the hypertrophies along the prostatic urethra . . . in other words, the extravescical or rectal enlargement as well as the intravesical projection."

But to remove "all the hypertrophies" does not in all cases involve a bilateral operation. It may be suggested that routine operations are not always good surgery, and that the infinite variety of pathological conditions should imply a corresponding flexibility and variability in surgical treatment. It has long been known that adenomatous enlargement of the prostate may be unilateral, but hitherto no practical conclusions have been drawn from this fact, and for such cases total prostatectomy has remained the rule. The object of this paper is to show that in unilateral cases Eugene Fuller's demand for the complete removal of all the hypertrophies can be fulfilled by a strictly unilateral operation—a hemiprostatectomy—restricted to the enlarged half of the prostate, and that complete relief of the urinary obstruction follows. *Prima facie* evidence is adduced that the unilateral operation is safer and simpler, and unattended by a serious degree of shock. It should certainly be preferred in all unilateral cases in which the immediate risk of a total enucleation appears greater than usual. Two such cases are here recorded, both operated upon this year and both in medical men. In the first case prostatectomy had been deferred by the patient's reluctance for eight years, with such deterioration of his condition that a well-known specialist recently advised permanent suprapubic drainage of the bladder. A further reason for caution was the dependence of the patient's family upon his Service pension. In the second case the

patient had only partially recovered from a complete hemiplegia of six months' standing.

I have performed hemiprostatectomy about six times. The records of my earlier cases, dating back perhaps fifteen years, are inaccessible owing to war conditions. But the evidence suffices to establish a *prima facie* case, perhaps all the stronger because I make no claims to specialist authority on the prostate. On the other hand, I have no apology to offer for my intrusion upon the urological domain. It is in my opinion essential for the future of surgery that general surgeons shall maintain their right of entry to the common lands which, with such success and advantage, have been fenced and cultivated by the various specialties. I recall with some satisfaction that at a Birmingham meeting of the Association of Surgeons I pointed out that clot retention in the bladder can be relieved by the intravesical injection per urethram of a few ounces of a peptonizing solution, without passing any urethral instrument. Received with scepticism at the time, this suggestion has since had specialist endorsement from Mr. E. W. Riches, who advises injection of 1 oz. of glyc. pepsini undiluted.

I am not prepared to deny that if the patient is a good risk it may be better, even in unilateral enlargement, to do a complete prostatectomy, so as to avert the possibility that the unaffected lobe may in later years undergo hypertrophy. The field of application of the unilateral operation is thus a restricted one, but in my opinion in about one case in five it may prove to be the operation of choice. It is generally admitted that the usual cause of urinary obstruction is the mutual lateral pressure of the two halves of the prostate. Remove the enlarged half and it seems unlikely that serious lateral pressure will recur, even if the remaining half of the prostate at a later date undergoes moderate hypertrophy. My limited clinical experience bears out this conclusion.

Recognition of Unilateral Hypertrophy

Rectal examination in these cases shows that the median prostatic sulcus does not divide the prostatic surface into equal halves. A lateral sweep of the finger-tip, first to the left and then to the right of the sulcus, as far as the prostatic margin, gives a fairly accurate measure of the relative size of the two parts, and enables a provisional diagnosis of unilaterality to be made. A cystoscopic examination shows that the urethra is not median in position with respect to the floor of the bladder. Frequently in unilateral enlargement a post-urethral "median lobe" is present—a protrusion from the enlarged lateral lobe; or an intravesical eminence may border the urethral margin laterally on the side of the enlargement. Final confirmation of unilaterality awaits bimanual examination when the

bladder has been opened. With one finger in the rectum and another in the bladder, and a bladder sound in position, a precise estimate of the relative size of the two lobes is easy. I must pause here to discuss what is the real nature of the operation known as prostatectomy.

Prostatectomy really an Adenectomy

The late Sir John Thomson-Walker said in the preface to his standard work, *Genito-Urinary Surgery*: "In recent works there is a tendency to slur over the science and to make prominent the art of urinary surgery. With this I am not in sympathy. It is, I believe, impossible to carry out good work on a superficial knowledge of the pathological conditions with which the surgeon has to deal." He goes on: "The pathology given in the following pages is not the pathology of the post-mortem room. It is the living pathology of the operating theatre, and as such is of vital importance to proper treatment."

His book was intended as an aid to clinical work, and his exclusion of post-mortem pathology was no doubt deliberate. But a discord which only post-mortem pathology can solve runs through prostatic literature even to the present day and bears directly upon the subject of this paper. On the one hand, authorities like Freyer and Thomson-Walker maintained or assumed that the operation of prostatectomy consists in the removal of the anatomical prostate with its capsule. Other authorities maintain that prostatectomy is really a prostatic adenectomy—a removal from the prostate of adenomatous masses. The "surgical capsule" of the adenoma, formed by pressure atrophy from the surrounding prostatic substance, remains in the body as the floor of the enucleation cavity. The supporters of the former opinion believe that the plane of separation in which the enucleating finger works lies between the anatomical prostatic capsule and the prostatic sheath of pelvic fascia. Those who support the latter opinion believe that enucleation is done in an intraprostatic plane—namely, the plane around the adenoma and just outside its proper capsule. The residuum of compressed prostate is left *in situ*.

There is no shadow of doubt that in some cases the operation done is the enucleation of an adenoma from the prostate. In Case 1, recorded here, there was enucleated from the left lobe, with complete relief of obstructive symptoms, an adenoma of the shape and size of the scaphoid bone of the carpus, with a median projection upwards into the bladder, a constriction corresponding to the grip of the internal sphincter, and a lower portion lying in the left lobe of the prostate. The tumour presented no feature of normal anatomy, and the prostatic urethra remained intact. Just as a uterine myoma may by a process of pressure atrophy free itself from the grip of the uterine muscle and become subserous or submucous, a prostatic adenoma may by a similar process come to lie just under the mucosa of the bladder or of the prostatic urethra. Its relations with the prostatic urethra may in some cases be so close that it may be impossible to take away the adenoma without also bringing away the adherent portion of the prostatic urethra. Some prostates come away in separate halves. In such cases an adenoma has formed in each lateral lobe, but the tumours have remained separate. Others come away as a single mass recognizable as resulting from the fusion of two adenomata behind the urethra, often with a middle lobe formed by the extension upwards of one of the lateral lobes. In front of the urethra the specimen shows no anterior commissure. The prostatic urethra may or may not be removed as part of the specimen. Yet other prostates come away as a single mass entirely surrounding the prostatic urethra, which is found complete, attached to the specimen, upon which the

anterior commissure is plainly recognizable. Such cases lend apparent support to the view that prostatectomy is the removal of the complete anatomical prostate. A case of this kind was investigated by W. G. Richardson of Newcastle as far back as 1904. Following the death of the patient a microscopical examination showed that the bed from which the tumour had been enucleated was composed of compressed prostatic tissue. Richardson asserts that after enucleation of prostatic tumours "a complete bed is always found composed of prostatic tissue, and the undamaged sheath of the prostate is always external to the bed." These observations of Richardson's are fundamental for prostatic surgery, and it is surprising that they have been ignored in the English literature of the subject up to the present time.

American opinion appears to uphold the view that prostatectomy is adenectomy. Prof. Hugh Cabot of the Mayo Foundation trenchantly says regarding Freyer's claim that his operation removed "the entire prostate with its capsule, the line of separation lying between the capsule and the recto-vesical sheath":

"This remarkable statement is, of course, quite without basis in anatomical fact. The operation which he did, and which was technically similar to that of Fuller, sought to enucleate the masses of fibro-adenomatous hyperplasia from within the prostate. The capsule to which Freyer referred was, of course, not the true capsule of the prostate, but what had for many years, at least in this country, been known as the 'surgical capsule' of the prostate. This consists of compressed prostatic tissue flattened by the growing masses of fibro-adenomatous hyperplasia."

This is exactly what Richardson proved in 1904 by his careful post-mortem work. Prostatectomy is adenectomy.

Analogy between Uterine Myoma and Prostatic Adenoma

Richardson says: "There appears to be an analogy between chronic enlargement of the prostate and myomata of the uterus. Both organs are essential to reproduction . . . during the declining years of fertile life both are specially liable to be affected by innocent growths of their essential tissues." It may be added that the analogy between adenomyoma of the uterus and adenoma of the prostate is especially close. The analogy must not be pressed too far. The uterus masculinus, and not the prostate, is the morphological equivalent of the uterus. Moreover, while total hysterectomy is easy, total removal of the prostate is a doubtful possibility. But the analogy does extend to surgical treatment. Hysterectomy is now often replaced by myomectomy. The replacement in unilateral cases of a bilateral adenectomy (prostatectomy) by a unilateral adenectomy (hemiprostatectomy) would be a parallel conservative development.

Frequency of Unilateral Enlargement

Thomson-Walker says: "Both lobes are usually enlarged to an equal degree, but one may be larger than the other, and, rarely, the enlargement may be confined to one lobe. In all such cases that I have examined the apparently normal lobe shows changes on section and microscopical examination which correspond exactly to those in the large lobe." These remarks seem not quite in accordance with the same author's statistical findings, based upon 54 enucleated prostates, with regard to the character of the intravesical projection (*Genito-Urinary Surgery*, p. 745).

(1) Median lobe alone	9
(2) Median and lateral lobes as a collar or distinct	18
(3) Both lateral lobes	15
(4) One lateral lobe	12
Total	54

From this table it seems possible to form an idea of the percentage of cases in which hemiprostatectomy may be

preferable to the bilateral operation. Cases in Groups 1 and 4 are candidates for the smaller operation, unless there is evidence that the lobe not projecting into the bladder is nevertheless enlarged. For the present no more precise statement upon the question is possible.

Advantages of Unilateral over Bilateral Operation

In the strictly unilateral adenomatous prostate it is meddlesome and unnecessary to remove the normal-sized lobe. To do so adds to the severity and risk of the operation without any compensating advantages except the remote and contingent ones to which I shall later refer.

The retention of the normal half of the prostate has great positive advantages. Along with it there is necessarily left the corresponding half of the prostatic urethra, forming along one side of the enucleation cavity a smooth epithelium-lined gutter guiding the urine from the bladder to the urethra. The continuity of the vesical and urethral mucous membranes—often interrupted in the bilateral operation—is maintained throughout. Nature's reconstruction of the complete tube must thus be assisted and facilitated. The residual half of the organ forms, in fact, a kind of splint or support for the enucleation cavity while it is healing and acquiring a new epithelial lining. The formation of a transverse post-prostatic bar obstructing the outflow of urine is impossible, since the residual half of the prostate holds the urethral outlet open and prevents the transverse fold of mucosa which corresponds to the posterior edge of the prostate from closing over it. The inner edge of the funnel formed by the removal of one lobe is supported and made rigid by the other lateral lobe, and so its patency is maintained.

Absence of Shock in Hemiprostatectomy

It is my experience that, except during the actual enucleation, which may cause some temporary disturbance of pulse and respiration, very little shock attends a hemiprostatectomy, even in old and feeble patients. I have done the operation but a few times, so that this must be regarded merely as a preliminary communication, but I have not lost a case. In the last case operated upon the pulse at the end of the operation was 84, and within a short time of the patient's return to bed it was 72 and of good volume. The evidence, so far as it goes, points to the greater safety of the limited operation, which has invariably proved fully efficient in restoring easy and painless micturition.

The nerve supply of a prostatic adenoma must be a rudimentary and improvised mechanism, if indeed such a tumour contains nerves at all—a point upon which no evidence appears to be available. On the other hand, the nerve apparatus of the prostatic urethra is a delicate and highly organized affair, having intimate relations with the higher centres of the cord and brain. The shock of prostatectomy is probably mainly due to urethral trauma. Though bilateral prostatectomy is possible in certain cases without injury to the prostatic urethra, as Freyer showed, it frequently involves great interference with, and sometimes complete removal of, this part of the urethra. It seems likely that the shock of prostatectomy is proportionate to the degree of injury to the prostatic urethra.

In hemiprostatectomy the urethra may remain quite uninjured. Even if it is so adherent to the adenoma that one lateral half of the prostatic urethra is removed, the degree of shock produced may be estimated as one-half the shock of a total prostatectomy. By safeguarding the integrity of the urethra so far as is possible hemiprostatectomy lessens the immediate risk of operation.

The First Hemiprostatectomy.—The first one on record appears to have been performed by W. G. Richardson about

1904. In a man suffering from signs of urinary obstruction an acute orchitis occurred. Abscess followed, and the left testicle atrophied. Fifteen months later Richardson "enucleated a large adenoma from the right half of the prostate, but there was only a minute tumour which was not enucleated in the left half" (*The Prostate Gland*, p. 85).

Middle-lobe Obstruction

In some cases though rectal enlargement of the prostate is not felt a middle lobe is seen with the cystoscope. Thomson-Walker showed that in most cases the middle lobe springs from one of the lateral lobes, and is due to incipient enlargement of that lateral lobe finding room by passing upwards in the direction of least resistance through the internal sphincter of the bladder. He also showed that obstruction to the passage of urine in such cases is not as a rule due to a corkage action of the middle lobe but to sideways pressure upon the prostatic urethra. These are in my opinion ideal cases for hemiprostatectomy.

Transurethral Resection versus Hemiprostatectomy

For such cases mere removal of the middle lobe is known to be unsatisfactory. The treatment of them by the Young punch or by urethral diathermy and removal piecemeal of the middle lobe and parts of one or both lateral lobes has proved safe and successful in the hands of a few experts. Nevertheless I believe that these median-lobe enlargements, belonging as most of them do to the strictly unilateral cases with which this paper is concerned, can be dealt with by unilateral enucleation with at least equal safety and success. What is accomplished by diathermy or transurethral resection is at best a partial removal of the adenomatous mass, the rest of which may continue to grow with a return of obstructive symptoms. In certain cases of this kind a prostatectomy has ultimately to be done, and the enucleation is made more difficult and dangerous by the fibrotic reaction of the tissues to the previous resection. Furthermore, it would seem that a clean enucleation of the enlarged lobe offers more security against later carcinoma.

With careful selection of cases the immediate mortality of transurethral resection is given by Mr. Kenneth Walker, who has done so much to develop the method, as under 5%. The period in hospital is about halved as compared with an enucleation. But, according to Mr. Walker, "there is a growing tendency among resectionists to avoid massive removal of tissue at one sitting, and to substitute when necessary several sessions for one." Thus in the long run the period of stay in hospital may not be reduced. He believes that perurethral resection is particularly indicated where it is the vesical rather than the urethral aspect of the prostate that is affected—for example, cases of obstruction due to an enlarged middle lobe, also for the small fibrous prostate, for carcinoma, and in the various forms of prostatic bar. I would dissent from his opinion only in regard to middle-lobe cases. He also says:

"The key to success in perurethral work lies in the careful selection of cases. It is because the method has been abused by certain enthusiasts that it has sometimes been brought into disrepute and its value lost sight of. It should be realized once for all that the perurethral approach is not a general substitute for prostatectomy; it is rather a method of treatment that is applicable to special types of case or to special circumstances."

Dr. Hugh Young, speaking with what must be a unique experience of all types of prostatic operation, but with a known preference for the perineal route, says:

"We are still convinced that in transurethral surgery by means of our prostatic excisor we have the safest method of attacking conditions for which it was originally offered—namely, contractions, bars, valves, median hypertrophies, valves of the posterior

The patient in January, 1941, had had an attack of complete hemiplegia, unattended by loss of consciousness, and could still walk only with difficulty and uncertainty. But his urinary discomforts were so great that I advised a cystotomy with a view to later hemiprostactectomy. A course of injections of staphylococcus "vaccoid" was given to minimize the risk of thrombosis. On June 29 I opened the bladder above the pubes, and removed about ten small uric acid calculi. A Mont-Blanc-like eminence occupied the right lateral vesical aspect of the prostate, but the left lobe appeared of normal size on bimanual examination. The bladder could not be entered by a coué catheter. The cystotomy caused little disturbance, and on July 8, under omopon and evipan given by Dr. C. H. Campbell Ferguson, I did a right unilateral adenectomy. The adenoma was easily enucleated and the shell of the right lobe was packed with vaselined gauze. A large coué catheter, which now passed quite easily, was tied in. At the end of the operation the pulse was 84, and within an hour of his return to bed it was 72 and of good volume. No rise of temperature followed the operation for some days, nor was there any sign of shock. Omission of bladder irrigation on the ninth day was followed by a rigor and pyrexia, but resumption of it brought the temperature down. The patient got up sixteen days after the operation. The bladder wound closed

on July 29, two days after an indwelling catheter was resumed, and on July 30 his pulse was a steady 72 and his temperature normal. The catheter was removed on July 31. Even before its removal fluid injected into the bladder by the catheter returned freely by the urethra outside the catheter. On July 31 a rigor occurred with a temperature of 105° and an acute right orchitis. With Dr. G. S. Haynes's concurrence sulphapyridine was given; the temperature fell in forty-eight hours, and subsequent convalescence was uneventful. Urine was passed naturally and easily after August 1, and the patient describes the stream as "better than normal."

The specimen after removal was an almost globular mass $4\frac{1}{2}$ cm. in diameter, and weighing 1½ oz. On section

Drawing of right half-prostate of Case 2; natural size, weight 1½ oz.

the mass was a typical adenoma without cysts. On the left aspect was visible, adherent to but separable from it, a smooth elastic band representing the right half of the prostatic urethra. Above, this broadened out to terminate in a torn edge at the urethral outlet of the bladder. Below, it narrowed to a point short of the verumontanum, where the urethra had been half torn across (see Fig.).

METHODS FOR THE LOCAL APPLICATION OF SULPHANILAMIDE

BY

FRANK HAWKING, D.M.

(From the National Institute of Medical Research, Hampstead)

Earlier papers have described the antibacterial effects of local applications of the sulphonamides to experimental wounds infected with the organisms of gas gangrene, and the concentrations in the blood and in the tissues around the wound resulting from such local applications (Hawking, 1941a, 1941b, 1941c). During this experimental work various practical methods have been devised, and these are here described in the hope that they may be helpful to those employing local applications of sulphonamide compounds to human lesions. For the sake of conciseness most references to other workers have been omitted. The compounds used have been either sulphanilamide or sulphathiazole.

Powder

In shallow open wounds this is the simplest form in which to apply the substance. It can be distributed by means of a spoon, a pepper-pot, or an insufflator. Whichever method is used, enough powder should be applied to cover the whole surface liberally, and yet not enough to form large concretions, which take a very long time to dissolve. Gently massaging the powder into the tissues with a spatula will help to get it effectively distributed and dissolved. For use in the operating theatre on fresh wounds it is convenient to have a supply of the powder in 5-gramme lots, put up either in paper packets or in screw-capped bottles. In order to obviate the very slight

risk of fortuitous contamination of the powder, during its manufacture or afterwards, by tetanus or other spores of pathogenic bacteria, it can be sterilized in such packets or bottles by dry heat at 150° C. for one hour. (If sterilized in the autoclave with the cap unscrewed the powder is apt to become crystalline and is no longer suitable for use in an insufflator.) For routine ward work the use of unsterilized powder would seem to be justifiable.

Gauze

In narrow deep sinuses which are packed at regular intervals with ribbon gauze the powder can be inserted into the depths on the packing. This can be done most simply by pouring the powder on to the gauze as it is pushed in, but a better way is to incorporate the powder on to the gauze beforehand. For this purpose small glass pots with a metal screw cap, such as are used for ointments, are taken. A wide slot is cut in the lid. The pot and the gauze are sterilized separately. The gauze is then passed through a thick paste of sulphanilamide and water under sterile precautions and is placed in the pot, the end of the ribbon protruding through the slot. The top of the pot is covered with a piece of sterile oiled silk. For use in the wards the ribbon is pulled out as required. If the gauze is autoclaved after smearing with the paste most of the sulphanilamide forms powdery crystals, which cease to adhere to the ribbon.

Tablets

It is difficult to transfer powder to the bottom of a deep sinus. The best method in these cases is the use of small tablets made of the compressed compound—e.g., tablets containing about 0.2 gramme of material and measuring about 8 mm. across. Such tablets were first suggested by Dr. A. S. Parkes; they were kindly prepared by the British Drug Houses Ltd. and May and Baker Ltd. The tablets can easily be inserted into the desired position by sinus forceps, and they are then crushed to hasten disintegration; eventually they are completely absorbed and leave no residue which might act as a foreign body. With sulphanilamide, which is fairly soluble, tablets of the pure compound will probably be dissolved in a reasonable time, although it is advantageous to crush them in order to accelerate the process. With sulphathiazole, tablets of the pure compound (uncrushed) were found to persist in a sinus for over two days without much visible change. It is better to use tablets consisting of 0.1 gramme of sulphathiazole and 0.1 gramme of glucose, the glucose being added in order to promote the disintegration of the tablet; when these are crushed after insertion most of the material is dissolved in twenty-four hours. Tablets could also be used in a wound when it was desired to secure a steady supply of sulphonamide over a prolonged period; by choosing tablets of an appropriate size the duration of action could be varied as required. The surface of the tablets can be sterilized by dry heat at 85° C. for one hour; heating to 115° C. causes the tablets which contain glucose to turn brown. This degree of sterilization will not kill spores, but the position is the same as that described for the powder.

Pastes

The results described in this section form the preliminary part of a wider programme, which will be described in more detail when it has been completed. Briefly, the ideal sulphanilamide paste for application to wounds, burns, etc., should have the following properties:

1. It should be satisfactory pharmaceutically—i.e., stable, non-odorous, non-rancid, etc.
2. Its physical consistency should be suitable for the required purpose; burnt surfaces might require a thinner preparation than that used for plugging wounds.

3. It should comprise only materials which are available under present war conditions. Thus, since cod-liver oil, which forms the base of two of the pastes described below, is now in short supply, a search for a suitable substitute forms part of the wider programme now in progress.

4. Sulphanilamide should be liberated from the paste at the optimum rate. Presumably the concentration of sulphanilamide in the fluid in contact with the paste should be as near saturation as possible, provided that: (a) The concentration is not so high as to injure growing tissues or to paralyse leucocytes. Jacoby, Medawar, and Willmer (1941) found that fibroblasts and macrophages are killed by a saturated solution of sulphanilamide (concentration 1:60), are temporarily depressed by concentrations of 1:150, and are not affected at all by concentrations of less than 1:1,000. According to these findings, it might be advantageous if the paste exerted a slight restraint on the rate of solution of the sulphanilamide. (b) The amount absorbed is not so great as to produce a toxic concentration in the blood; probably this will not occur except when the areas to be dressed are large; it can be decided only by blood estimations of treated patients. (In a private communication Colebrook reports that one patient who was treated by sulphanilamide paste for a very extensive burn became cyanotic, and the concentration of compound in the blood was 8 mg. per 100 ml.) The whole question is under investigation.

It may here be noted that mixtures of sulphanilamide and liquid paraffin appear to be in use in some hospitals. According to experiments in this laboratory sulphanilamide is insoluble in paraffin and cannot diffuse across it. In mixtures of paraffin and sulphanilamide, however, the particles of sulphanilamide usually sink to the bottom of the paraffin layer until they come into contact with the underlying watery fluids, in which they dissolve. Hence, if sulphanilamide suspended in paraffin is injected into rabbits subcutaneously it is absorbed almost as quickly as if it were suspended in saline. This occurs because the mixture is unstable and in the body it separates into its component parts; if this separation were prevented—for example, by using petroleum jelly—little or no absorption would presumably take place.

5. The paste should be non-irritant to the tissues and innocuous to leucocytes. It should not delay healing; rather, if possible, it should stimulate it.

The complete solution of all these problems will take a considerable time, and meanwhile casualties occur which require treatment. Therefore this short description is given of the best pastes which have been found to date so that they may be available in hospitals, and clinical experience may be gained which may help to orientate the further researches in hand. For the pharmaceutical side of the present work I am indebted to the British Drug Houses Ltd., who kindly co-operated with their experience in these matters and devised pastes of different properties for my trial. The physiological action of these pastes was tested by injecting them between the muscles of rabbits and into the peritoneum of rats; the irritation which they caused was not appreciably greater than would have been produced by any foreign body in these positions. Three pastes are provisionally recommended to suit three different types of lesion.

1. *Sulphanilamide, 30% ; oleic acid, 1.4% ; triethanolamine, 0.35% ; cetyl alcohol and beeswax, each 1.4% ; water to 100%.*—This is a thin paste to spread over inflamed skin surfaces—e.g., impetigo—in order to apply sulphanilamide with as little other material as possible. It can be used on granulation tissue instead of powdered sulphanilamide, but if inserted into deep wounds it leaves a residue. The sulphanilamide is absorbed from this paste almost as rapidly as when the powdered compound is applied as such. This paste was kindly tested by Dr. A. Glucksmann of the Strangeways Laboratories, who applied it every other day to standard wounds in rats. He found that it caused very

slight irritation, as shown by stimulation of collagen regeneration and slight retardation of epithelial regeneration; but this irritation was so slight as to be unimportant compared with bacterial infection.

2. *Sulphanilamide, 30% ; cod-liver oil, 49% ; oleic acid, 3.5% ; triethanolamine, 1.05% ; cetyl alcohol, beeswax, and other ingredients to diminish rancidity, 3.5% ; water to 100%.*—This is a paste of medium consistency. The absorption of sulphanilamide from it proceeds slightly more slowly than that which occurs when the compound is applied as a simple powder. Besides supplying a large depot of sulphanilamide, which will be taken up by any serous exudate to form an almost saturated solution, a paste of this kind provides an oily protective layer and will also prevent sticking of dressings. This paste was designed especially for the treatment of burns. Colebrook (personal communication) has observed the rapid disappearance of haemolytic streptococci following its use in such injuries; he also found that it is unnecessary to change the dressings more often than every two, or three days. Robson and Wallace (1941) have reported very satisfactory results in burns treated with a similar paste made up with albucid (*p*-aminobenzenesulphonacetamide), which is considerably more soluble than sulphanilamide and which accordingly may exert a greater effect upon the less sensitive organisms such as staphylococci and *Ps. pyocyanea*.

3. *Sulphanilamide, 30% ; cod-liver oil, 60% ; beeswax, 10%.*—This is a stiff paste, to be used on gauze for packing wounds, in the same way as vaselined gauze is used. Its consistency can be modified by varying the proportions of cod-liver oil and beeswax. It provides a non-irritant, non-adhesive mechanical support to the sides of the wound, and at the same time gives off a supply of sulphanilamide, liberation of the compound being slow. It tends to become rancid, however, unless preventive measures are taken.

Summary

Methods are described for the local application of sulphanilamide: (a) as a powder to open wounds; (b) as tablets or on gauze to deep sinuses; (c) as various kinds of paste to treat inflamed surfaces, burns, and wounds which must be packed.

Details are given of three pastes which may be recommended for use in three different types of lesion.

Acknowledgments are due to Colonel L. Colebrook for inspiration and advice; to the surgical staff of the New End Hospital, Hampstead, for facilities; to Miss M. Kuck for technical assistance; and to the British Drug Houses Ltd. for co-operation in devising and preparing the pastes.

M. B. Gordon, N. H. Solomon, and S. F. Pearlman (*J. Pediatr.* 1941, 19, 76) record their observations on 680 scarlet fever patients aged from 10 months to 41 years, most of them being between 8 and 21 years of age. They classify these cases into the three groups of mild, moderate, and severe. The mild cases were divided into two groups: (a) controls and (b) those treated with sulphanilamide. The moderate cases were divided into four groups: (a) controls, (b) those treated with sulphanilamide, (c) those treated with scarlet fever antitoxin, and (d) those treated with sulphanilamide plus scarlet fever antitoxin. The authors' conclusions are as follows: (1) Sulphanilamide reduces the incidence and severity of complications. (2) Scarlet fever antitoxin reduces the length of the febrile period to a further extent than sulphanilamide, but it is not so effective as sulphanilamide in reducing the incidence of complications; the combination of scarlet fever antitoxin and sulphanilamide offers better results than sulphanilamide or scarlet fever antitoxin alone. (3) The toxic effects of sulphanilamide are not grave enough to contraindicate its use in scarlet fever.

TREATMENT OF DIPHThERIA CARRIERS WITH SULPHATHIAZOLE SNUFF*

BY

A. M. THOMAS, M.A., M.B., B.Ch.

Pathologist, E.M.S.

Delafield, Straker, and Topley (1941) have described the effects of antiseptic snuffs on the nasal flora of healthy subjects, and demonstrated an effective if temporary reduction in numbers of potential pathogens. At the end of December, 1940, Professor W. W. C. Topley kindly supplied me with a sample of sulphathiazole snuff for trial on nasal carriers in an isolation hospital. Twenty-eight subjects who were harbouring *Corynebacterium diphtheriae* or other pathogens in the nose were tested with the snuff. Ten per cent. sulphathiazole in magnesium carbonate was used for 26 cases and 33% sulphathiazole in magnesium carbonate for the other 2. The snuff was given six times a day on a small piece of paper, a separate piece being used each time for each child, to avoid passing infection. In all cases except one at least two nasal swabs were taken before treatment was started, in order to give a rough indication of the numbers of *C. diphtheriae* and other organisms present. In most cases a week elapsed before the next swab, which was the first to be taken during snuff treatment; subsequent swabs were taken twice weekly.

In order to reduce to a minimum the sampling errors due to dryness of the nose, the swabs were moistened with sterile broth immediately before use. The moistened swab was originally instituted because the snuff itself was thought to have a drying action on the nasal mucosa, but this was not found in all cases. However, in a few tests, moistening the swabs produced an increase in growth in five cases out of six. Dry swabs and moistened swabs were taken from the same persons on consecutive days. In one instance a moistened swab yielded one colony of *C. diphtheriae* where the dry swab gave none; one moistened swab produced a heavy confluent growth of *Staphylococcus pyogenes* (coagulase-positive) where the dry swab had yielded two colonies of *Staph. pyogenes* and two of *Streptococcus pyogenes* (Lancefield's Group A). The increase was less noticeable in three other cases, and in one instance the dry swab gave a confluent growth of *Staph. pyogenes* where the moist swab gave only 42 colonies.

Each swab was inoculated on to a blood-agar plate, a Gaze's serum tellurite plate, and a Loeffler's slope, in that order; the blood plate was inoculated first so that the effect of the snuff on the nasal flora as a whole might be as clear as possible.

At the beginning of treatment 8 subjects carried *Staph. pyogenes* alone, 10 carried *C. diphtheriae* and *Staph. pyogenes*, 2 carried *C. diphtheriae* and *Str. pyogenes*, 1 carried *Staph. pyogenes* and *Str. pyogenes*, and 6 carried all three organisms. One subject carried only *C. hoffmanni* and *N. catarrhalis*. The results of treatment are summarized in the following table:

Table showing Effect of Sulphathiazole Snuff on Nasal Pathogens

	<i>C. diphtheriae</i>	<i>Str. pyogenes</i>	<i>Staph. pyogenes</i>
No. of cases carrying	29	12	25
(a) No. showing immediate clearance	12	6	17
(b) No. showing delayed clearance	3	3	4
(c) No. showing irregular clearance	5	3	4*

* Indicating considerable reduction in numbers but not complete clearance.

Quantitative representation of results is greatly complicated by the use of two media, especially as one is highly

selective; consequently a compromise scheme has been adopted. The approximate numbers of colonies on blood-agar plates after twenty-four hours' incubation, or on tellurite plates after forty-eight hours' incubation, are represented along the ordinates of all the charts by plus signs, which signify as follows:

++++ = approx. 101-500 colonies on blood-agar plates
 +++ = " 51-100 " " " " " " or a heavy growth on tellurite plates
 ++ = " 1-50 " " " " " "
 + = No colonies on blood-agar plates, but a few colonies on tellurite plates only
 0 = No colonies on either plate

Results with Nasal Carriers of *C. diphtheriae*

(a) Cases showing Immediate Clearance after Snuff (12 out of 20).—Eight patients showed a marked change, the colonies of *C. diphtheriae* on the blood-agar plate falling from between 90% and 10% of the total colonies to nil. Chart I is typical of this response. Nasal swabs from the remaining four persons, taken immediately before treat-

CHART I

Indications for charts:—x...x. *Str. pyogenes*; +...+, *C. diphtheriae*; G=Gravis; M=Mitis (virulent).

ment was started, yielded at the most a moderate number of *C. diphtheriae* colonies; in fact, they were poor subjects for demonstrating any gross change, but nevertheless they, like the other four, were cleared. Chart II illustrates this type of change.

CHART II

(b) Cases showing Delayed Clearance (3 out of 20).—Three patients continued to carry *C. diphtheriae* in large numbers during at least a fortnight of treatment. One of

CHART III

these was an infant aged 2 months (Chart III), and in this instance the success of the administration of the snuff is in doubt, since the *Staph. pyogenes* of the nose were not reduced in numbers: although it is possible to make an infant sniff at a proffered powder by forcibly shutting its mouth, this does not ensure adequate or regular dosage. In the two older children the numbers of the other organisms were eventually reduced in quite typical fashion, simultaneously with the decline in the numbers of *C. diphtheriae*, as if the snuff action had been delayed.

(c) Cases showing Irregular Clearance (5 out of 20).—The remaining 5 patients during treatment produced

occasional nasal swabs which yielded a few colonies of *C. diphtheriae* on tellurite plates only (Chart IV).

Follow-up Swabs.—On account of the children being discharged from hospital when clear and passing out of reach of the laboratory, difficulty was experienced in obtaining swabs taken after the cessation of snuff treatment. This was achieved in 4 diphtheria and 9 staphylococcal carriers. Three children, one in Group (b) and two in Group (c), who gave an unsatisfactory or equivocal response

CHART IV

to the snuff, but who were eventually discharged free from *C. diphtheriae*, were found later to be nasal carriers. One child had two and the others three clear nasal swabs before discharge; when swabbed 10, 49, and 60 days respectively after the cessation of snuff they were found to harbour a moderate number of *C. diphtheriae* in nose and throat. Three out of 20 is probably a high proportion of cleared carriers to yield positive swabs more than a week after discharge, and it is obvious that any antiseptic snuff may produce only a transient absence of *C. diphtheriae* from swabs. This is particularly liable to happen when, as during this investigation, there was no interruption of snuff treatment for twelve hours before swabbing, as recommended by Delafield and Straker. In the present investigation swabs were taken at 9 a.m., snuff having been given at 6 a.m.

Types of *C. diphtheriae*.—At the beginning of treatment 14 subjects were carrying *C. diphtheriae* of "gravis" type, 5 of "mitis" type, and one of both types. Ten gravis and 2 mitis carriers were cleared, and 1 gravis and 2 mitis carriers were unaffected; the remaining 5 gave an equivocal response. Five subjects out of 20 showed change of type, all from gravis to mitis, indicating considerable cross-infection.

SIGNIFICANCE OF RESULTS

A general idea of the efficacy of the snuff with *C. diphtheriae* may be gathered from the following considerations. The nasal flora of 24 carriers of *C. diphtheriae* was followed for periods varying from four to fourteen weeks until the diphtheria bacillus disappeared and the patients were discharged. These carriers received no snuff, and serve as a control group. The most striking feature of the snuff treatment was the rapid effect on very heavy carriers. Confining ourselves to this type of patient, 18 heavy carriers were found in the control group, and an examination of their charts showed that a sudden final decline from +++ to no colonies of *C. diphtheriae* in a week or less (as, for example, in Chart I) occurred in 6 out of the 18. Of the 20 snuff-treated cases, only 10 were heavy carriers, and all of them showed a sudden final decline from +++ to nil; in 7 it immediately followed the administration of the snuff, and in 3 (Group c) it occurred fourteen to twenty-four days after the beginning of snuff treatment. If the figures for the control group are taken as representative 33% (6 out of 18) of the treated heavy carriers would be expected naturally to exhibit a sudden final decline. The fact that 70% of the treated heavy carriers did so suggests that the snuff was effective, though the difference between the two groups is not statistically significant. (The difference is 2.3 times its standard error.)

But if we assume that the sudden decline in the treated group was natural it is highly unlikely that in 7 cases out of 10 the administration of the snuff should have been decided upon at the moment a natural decline was due and in 3 cases some fourteen to twenty-three days before it was due. In the absence of more clear control data it is justifiable to assume that the sulphathiazole snuff was responsible for the marked effect that followed its use.

Results with Nasal Carriers of *Staph. pyogenes*

Observations on *Staph. pyogenes*, apart from their direct interest, are of considerable value as an index of satisfactory or unsatisfactory inhalation of the snuff. *Staph. pyogenes* was present, usually in large numbers, in the noses of 75% of the occupants of the diphtheria wards, and so is obviously the indicator organism of choice. Sulphathiazole snuff produced an immediate and marked reduction in the numbers of the organism carried by 17 out of 25 subjects. The reduction was generally from a heavy confluent growth to about half a dozen colonies; on some occasions the heavy growth of *Staph. pyogenes* was replaced by a few colonies of *Staph. albus*. These findings are in agreement with those of Delafield and Straker.

Of the four failures with *Staph. pyogenes*, three occurred in the three subjects who persistently carried *C. diphtheriae* (Group (b), see above). The failure in these cases to reduce in numbers the indicator organism casts doubt upon the successful administration of the snuff.

When the snuff treatment was stopped 3 subjects out of 9 showed a relapse to their original state of heavy carriage after a fortnight.

Results with Nasal Carriers of *Str. pyogenes*

In 6 out of 12 cases the snuff produced an immediate reduction in numbers of *Str. pyogenes* carried. Three subjects continued to carry the organism in considerable numbers. One child (Chart IV) yielded persistently heavy growths of *Str. pyogenes* and only moderate or scanty growths of *Staph. pyogenes* and *C. diphtheriae*. This child had a heavily crusted nose, and it is unlikely that the snuff made adequate contact with the nasal organisms. The carriage of *Str. pyogenes* in the occupants of the diphtheria wards was very irregular throughout the winter, and liable to sudden fluctuations, possibly on account of cross-infection, the occurrence of which with other organisms is suggested by changes in the type of *C. diphtheriae* noted in five carriers.

Summary and Conclusions

The results of treatment of 20 nasal carriers of *C. diphtheriae* with sulphathiazole snuff are promising but not uniformly successful; while in 12 cases the nasal cavity was immediately and finally cleared of *C. diphtheriae*, 3 showed no apparent response for at least a fortnight, and in 5 the response was irregular. Three patients who did not respond immediately to the snuff but who were subsequently discharged from hospital free of *C. diphtheriae* were later found to harbour this organism. Except for two cases, only 10% sulphathiazole snuff was used. Delafield and Straker have recommended 33% sulphathiazole snuff for diphtheria carriers; and, indeed, the two patients in the present series treated with it gave a highly satisfactory response, as shown in Chart I.

The snuff tends to produce a reduction in numbers of *Staph. pyogenes* rather than clearance, which is in agreement with the findings of Delafield and Straker. However, even partial success, producing only a temporary clearing or a reduction in number of pathogens, is undoubtedly of considerable value in minimizing cross-infection in wards by reducing numbers of pathogens.

sprayed in the air. It may also prevent inhaled cross-infecting organisms from establishing themselves in the nose.

An obvious reason for failure is lack of contact between the sulphathiazole and organisms, and there are at least three different ways in which contact may be prevented:

1. Failure to administer the snuff successfully to the very young, particularly if the nasal passages are partly blocked as a result of catarrh, crusting, etc.

2. Heavy crusting in the nose, preventing contact between snuff and organism even after effective inhalation of snuff. The necessity for this thorough contact was stressed by Col. Colebrook when dealing with the dressing of war wounds with sulphonamide powders; he pointed out the need for a thorough wound toilet and a prompt application of powder before the surface of the wound has time to dry and become coated with fibrin. In the nose the same problem presents itself, and it might be beneficial, at least in resistant cases, to perform some kind of nasal toilet immediately before giving the snuff.

3. Presence of *C. diphtheriae* in the nasal sinuses; the snuff would be unlikely to penetrate so far regularly or in quantities sufficient to clear them.

In cases of failure of treatment there still remains the possibility of sulphathiazole-resistant strains of *C. diphtheriae*. However, a study of the rest of the nasal flora is of value here, because, unless this is reduced quantitatively and the *C. diphtheriae* continues to flourish, there are probably some of the above factors at work.

This investigation represents a trial of sulphathiazole under field conditions, and is an attempt to glean information from routine specimens rather than from a carefully planned scheme. The snuff was originally given to subjects who were known to be heavy and long-standing nasal carriers of *Staph. pyogenes*, to find out the effect of this organism. Only incidentally were the effects on *C. diphtheriae*, *Str. pyogenes*, and other organisms noted; these effects appeared pronounced enough to warrant publication. Subsequently diphtheria infection in the district declined, and it was not possible to investigate the problem satisfactorily by a comparison of treated and controlled groups of cases; accordingly the graphic representation of results before and after treatment has been adopted. Considerable difficulty has been experienced as the result of separation of the laboratory and the wards; it is particularly desirable in an investigation of this type to co-ordinate the clinical and laboratory findings. It should be emphasized that the use of an effective snuff in the treatment of diphtheria carriers and convalescents should not be the signal for relaxation of measures designed to prevent the spread of ward infection.

I am indebted to Dr. W. J. Cox, medical officer of health for Watford, for his co-operation and for the facilities extended to me; to Prof. W. W. C. Topley for a supply of snuff; and to Prof. A. A. Miles for his advice and encouragement.

Dr. Henry F. Vaughan, health commissioner of Detroit, has been appointed professor of public health at the University of Michigan, where he will also take part in planning for a new building and organization of a school of public health. The Kellogg Foundation and the Rockefeller Foundation have undertaken to co-operate in the project, each agreeing to pay £100,000 for the establishment of the school. Not more than half of the total sum will be available for site, building, and equipment; the remainder will be spread over a ten-year period for the initial expenses of the school.

THE NUTRITIVE VALUE OF BREAD

FORTIFIED WHITE FLOUR AND NATIONAL WHEATMEAL COMPARED

BY

MARGARET D. WRIGHT, B.A., M.B., B.S.

Despite the importance of estimating the relative nutritive values of the two alternative wartime flours—national wheatmeal of 85% extraction and white flour of 75% extraction fortified with vitamin B₁—experimental work on the subject is not yet extensive. Wholemeal bread, with its higher content of the vitamin-B₁ complex, of vitamin E, and of iron, would appear from a nutritive point of view to have definite advantages.

Dr. Chick's Experiment with White and Wholemeal Bread

Dr. Harriette Chick (1940), describing an experiment in which the two flours were compared by the growth response of young rats, concluded that the advantage lies with wholemeal flour. She summarizes her findings as follows: "The nutritive value of a straight-run white flour [73% extraction] tested on young growing rats has been found inferior to that of wholemeal flour [82% extraction], even when the defects of the former in protein, minerals, and vitamin B₁ have been corrected. The inferiority must be attributed to lack of B₁ vitamins."

The experimental work which led to these conclusions may be described very briefly as a comparison of the effects on the growth of nine young rats of two diets, one based on straight-run white flour of 73% extraction (not 75%, as at present in use), the other based on "wholemeal" flour of 82% extraction (not the 85% wheatmeal now being advocated). In view of its slightly higher protein content compared with white flour (13% against 12.1%), the wholemeal flour was fed at the lower level of 82% against 88% for the white flour, the balance being restored so far as carbohydrate is concerned by the addition of 6% of pure maize starch to the wholemeal diet. The two diets were alike in all other respects, except that to each rat on the white-flour diet there was given daily by pipette 10 microgrammes of pure vitamin B₁, this being regarded as an optimal amount.

Examination of the numerical results given for the average weekly gains in weight shows that the rats on the wholemeal-flour diet grew much faster than those on the white-flour diet, and at first sight these figures are impressive. On closer investigation, however, it is seen that during the first week the food intake of the rats on the white-flour diet was much lower than that of rats on the "wholemeal" diet. While this may have been due to nothing more than differences in palatability—since the animals' appetites were presumably normal on their B₁ intake—it nevertheless follows that the carefully computed theoretical equality of protein intake was not attained in practice: the rats on the white-flour diet received 6.25 grammes of protein in the first week, whereas the rats on the wholemeal-flour diet received 9.09 grammes of protein (of a slightly higher biological value). The figures for the second week were 6.8 grammes for rats on the white-flour diet and 10.3 grammes for those on the "wholemeal" diet. It should be observed that this differential intake of protein for the first and second weeks can have been due to nothing more than inacceptability of the white-bread diet to the rat palate. The effect of such a wide difference in protein intake, in a growth-rate experiment designed to be crucial as to the relative value of the diets in other respects, is fundamental.

Certain other possibly less important points appear to arise. Having regard to the food intake of the animals concerned, 82% of "wholemeal" flour—assuming a value of 1 I.U. per gramme—should provide approximately twice as much vitamin B₁ daily as was received by the rats on the white-flour diet. As already stated, 10 microgrammes (3½ I.U.) has been regarded as optimal for these animals, but in such a comparison as is

now being made it should not pass unnoticed that the other group of rats was receiving approximately 6 I.U. of vitamin B₁ daily.

It should be noted that although Dr. Chick attributed her findings to an inferiority of the B₂ vitamins in the white-flour diet, this diet was much inferior to the other in vitamin E also. Published findings on the subject are scanty, and Olcott and Mattill (1937) record the same rate of growth in young rats on an E-deficient as on an E-adequate diet. Yet it is known that adult rats reach a lower maximum weight on diets deficient in vitamin E; the comparison between the two flours in respect of the B₂ vitamins would have been closer if the requirements for vitamin E of rats on the white-flour diet had been satisfied. It has also been shown that vitamin E is not without influence on the fate of vitamin A in the body (Davies and Moore, 1941).

In view of the small number of animals employed (nine in all) we should have liked to examine the significance of the differences between the growths of the rats on the two diets; it has not proved possible to do this, since figures for individual rats are not given. The four points so far enumerated are:

1. The quantitative shortage of protein and of all other ingredients of the white-flour diet during the first and second weeks of the experiment.
2. The imbalance of the diets in respect of vitamin B₁.
3. Their imbalance in respect of vitamin E.
4. The fact that it has not been possible to assess statistically the significance or otherwise of the findings.

Of these points, the only one which would probably be generally regarded as of sufficient weight to throw doubt on Dr. Chick's conclusions is the first, although it is unfortunate from the point of view of the findings of the experiment that the other, minor, objections both operate in favour of the "wholemeal" diet and against the white. The cause of the differences in protein intake in the first and second weeks was clearly the contrast between the two diets in palatability to the rat.

The fundamental nature of this objection is perhaps best appreciated by considering the situation which would arise were it possible to carry out feeding experiments on a sufficiently large number of human subjects. It is generally agreed that white bread is more widely acceptable, and in an *ad lib.* test on growing children the advantage might therefore for this reason well appear to be with white bread. It is clear that such an experiment would not be regarded as conclusive in respect of the relative nutritive values of the two breads. For such a comparison equality of intake is essential. For this and the other reasons already cited it was decided to undertake further work on the relative values of the two main flours suggested for general use under more nearly equal conditions.

First Experiment, comparing Fortified White Flour and National Wheatmeal

Thus, although the work planned was, like Dr. Chick's, a comparative study of the nutritive values of a high-extraction flour and a white flour whose deficiencies of vitamin B₁, protein, and mineral salts were made good, the bases of the diets differed. The materials used in this test were white flour of 75% extraction fortified with 0.2 gramme of aneurin per 280-lb. sack, and national wheatmeal of 85% extraction. Both were purchased direct from one of the largest plant bakeries in North-West London.

	% Ash	% Protein
White flour, 75% extraction	0.53	N ₂ 2.27 × 5.7
Wheatmeal, 85% extraction	0.86	N ₂ 2.39 × 5.7

All previous tests on flours appear to have been carried out with the flour either untreated or cooked by steaming, as was done in Dr. Chick's work; but, since flour is always eaten after cooking and the vast bulk is consumed baked into bread, it seemed that the results obtained would be more directly applicable to human nutrition if the experi-

mental diets were also baked into loaves before feeding. It was necessary to add a small quantity of baker's yeast containing the other vitamins of the B complex. This was not regarded as a disadvantage, since yeast is so widely used in bread-making—contributing, in the quantities generally employed, an addition of vitamins insignificant in human nutrition. The diets were as follows:

- 400 grammes of flour (fortified white of 75% extraction or national wheatmeal).
- 27 grammes of G.L. ashless extracted casein.
- 18 grammes of arachis oil.
- 9 grammes of McCollum's salt mixture.
- 12 grammes of yeast.

The iron in the salt mixture compensated for the deficiency of this mineral in white bread. The yeast used throughout the test was identical and the baking conditions were kept constant.

Young black-and-white rats of our own inbred laboratory strain weighing 36 to 54 grammes were used. They were divided into groups, each group composed of rats as similar as possible, with the sexes and litter-mates proportionately distributed. Two groups were given the diets described, and in addition each rat received daily a drop of cod-liver oil in which α -tocopherol had been mixed at the rate of 170 mg. in 6 oz. of oil. The rats were caged separately. The test lasted for thirty-three days, beginning when the rats were 4 weeks old.

The vitamin B₁ content of white flour of 75% extraction is about 42 units per 100 grammes. The addition of 0.2 gramme aneurin per sack would add approximately 52 units per 100 grammes, thus making a total of 90 to 95 units. The wheatmeal contained 109 units per 100 grammes. Allowing for the water added to mix the diets—more was used for the wheatmeal than for the white-flour loaves—and for some loss in baking, the vitamin B₁ contents found were in accordance with expectations. Thiochrome assays of the two foods showed very comparable vitamin B₁ contents, tests on the baked loaves giving values between 57 and 61 units per 100 grammes.

The wheatmeal loaves had approximately 3% higher moisture content than the white loaves, and allowance was made for this in weighing the slices for the animals. It would have been desirable to add a flavouring agent to both diets to equalize their palatability and thus increase the total intake of food; but since no means of doing this was known it was decided to restrict the intake where necessary, so that all rats consumed approximately equal amounts of food. This was accomplished in practice by always feeding the rats as soon as those eating at the slowest rate had finished or practically finished their previous feed. The animals on the wheatmeal diet always consumed their share before those of the other group.

The weight gains throughout the period of tests were as follows:

TABLE I.—Weight Gains

Diet containing Fortified White Flour		Diet containing Wheatmeal Flour	
49 gm.	Mean of 10 = 63.9 gm. σ = 9.67 t = 3.058	48 gm.	Mean of 15 = 66.5 gm. σ = 7.6 t = 1.517
56 "		51 "	
58 "		52 "	
58 "		56 "	
62 "		58 "	
64 "		58 "	
67 "		59 "	
69 "		61 "	
73 "		62 "	
83 "		64 "	
		65 "	
		65 "	
		67 "	
		68 "	
		74 "	

TABLE II

	Total Food Fed Throughout the Test (Av. per Rat)	Dry Weight of the Food Given (Av. per Rat)	Dry Weight of the Food Wasted (Av. per Rat)	Food Residue Uneaten at End of Test (Av. per Rat)	Actual Intake of Food
Fortified white-bread diet	388 gm.	229.3 gm.	19.3 gm.	6.4 gm.	203.6 gm.
Wheatmeal-bread diet	406 gm.	226.9 gm.	14.3 gm.	1.6 gm.	211.0 gm.

This corresponds to an average weight increase of 1 gramme from a consumption of 3.19 grammes of the white-bread diet and from 3.48 grammes of the wheatmeal diet.

A study of the figures given in Table I shows that there is no significant difference between the gains in weight made by the two groups of animals. The average growth rate is about seven-tenths of the normal for rats of this strain on an unrestricted intake of their adequate stock diet, which is what would be expected having regard to the restriction of food intake in the present test.

Second Experiment: Application to Human Diets

When the experiment just described was being planned it was thought that if its results should show a definite difference between the nutritive values of the two flours it might still be held that this would lose its significance when considering the application to human diets, since man consumes a range of foods not commonly used in laboratory experiments. Concurrently with the first experiment, a second was therefore planned to see how rats would thrive on the same two flours, when these were baked into bread and used as a percentage of an ordinary human mixed diet. It was not possible to obtain figures of the wartime consumption of the standard foods, but a formula was chosen based upon the estimated consumption in 1934 (Sir John Orr, 1937) modified, in conformity with present-day rationing arrangements, by reducing the amounts of meat, fish, and eggs, and including greater quantities of potatoes, vegetables, and bread. The diets were as follows:

Bread (fortified white of 75% extraction or wheatmeal of 85% extraction)	35.5%	Margarine	3.0%
Boiled potato	30.0%	Cheese	0.7%
Cooked meat	6.0%	Cooked vegetables	14.0%
Fresh milk	3.0%	Jam	1.2%
Cooked fish	3.0%	Eggs	1.2%
		Sugar	2.4%

The bread was crumbed and the other foods were minced. Three batches of food were prepared during the four-weeks test and, except when required for weighing, were kept refrigerated. The meat used was beef on two occasions and mutton on the third. The vegetables were cooked cabbage and other greens; 1 oz. of raw lettuce was included in each batch. The fish was canned herring on the first occasion, canned salmon on the second, and fresh cooked herring for the third batch. The ingredients were mixed by prolonged hand-kneading, and this was continued for half an hour after the diet looked and felt uniformly mixed. Even so, the analysis suggests that the constituents were not distributed perfectly evenly throughout the whole.

The analyses of the diets were as follows:

	White (75% extraction)	Wheatmeal (85% extraction)
Protein	8.81	8.15
Oil	6.09	5.09
Ash	0.63	0.67
H ₂ O	54.30	55.10
Ca	0.19	0.10
P	0.07	0.20

The rats were given these diets for four weeks, beginning when they were 4 weeks old. They were caged singly and

weighed weekly, being fed weighed quantities of food as soon as all the rats had completely or almost completely finished the last batch.

The weight gains were as follows:

Mixed Diet, with White Bread	Mixed Diet, with Wheatmeal Bread
65 gm.	59 gm.
59 ..	59 ..
59 ..	66 ..
59 ..	68 ..
61 ..	68 ..
65 ..	71 ..
65 ..	71 ..
72 ..	72 ..
73 ..	73 ..
75 ..	76 ..
81 ..	84 ..
Mean = 65.54 gm.	Mean = 69.64 gm.
$\sigma = 8.35$	$\sigma = 7.30$
$\epsilon = 2.52$	$\epsilon = 2.20$

$$t = 1.23; P = 0.23.$$

Each rat received 603 grammes of food during the four-weeks test. The total food wastage (dry weight) of the two groups was very similar—165 grammes for the white-diet group and 151 grammes for the wheatmeal-diet group. There was no residue to deduct at the end.

Discussion

McCarrison's well-known work demonstrated that young rats thrived very badly on a mixed diet containing unfortified white bread, mixed with the other staple foods characteristic of those used by the poorest people in this country. The animals showed all the signs of vitamin-B deficiency, and some were ultimately killed and eaten by their fellows.

In the present test, using fortified white bread, no doubt of higher extraction than was used by McCarrison, the results were entirely different. The animals grew and showed every sign of health. Comparison of the growth increments of the two experimental groups shows that between the ages of 4 and 8 weeks rat growth appears to be equally well supported by wheatmeal of 85% extraction or by white flour of 75% extraction fortified with vitamin B, when these are mixed with the staple foods into the diets previously described.

Fifty ounces of the mixed diet made up with white bread supplies 2,600 calories, 0.46 gramme calcium, and 79.3 grammes of protein, of which 32.3 grammes is of animal origin. It would thus resemble the diets of Orr's Groups I and II (Orr, 1937) (the lowest-paid groups of the population).

	Calories	Total Protein	Animal Protein	Calcium
Group I (Orr)	2,317	71.6 gm.	50.7 gm.	0.37 gm.
Present experimental mixed diet (50 oz.)	2,600	79.3 gm.	32.3 gm.	0.46 gm.
Group II (Orr)	2,768	93.8 gm.	80.9 gm.	0.52 gm.

* By calculation.

This particular diet, it should be noted, contains more bread (17.75 oz.) than the average pre-war intake throughout the country (12 oz. daily per head). The riboflavin supplied by these foods in the 2,600-calorie diet would amount to 0.93 mg. (figures from Fixsen and Roscoe, 1940; also some, unpublished, from Dr. Magnus Pyke). Slightly over 16% of this is given by the admittedly large amount of bread. If this were all in the form of wheatmeal the riboflavin it supplies would rise to 23%. The potatoes and vegetables between them supply over 43% of the total riboflavin. The large amounts of bread, potatoes, and vegetables in this diet, and its low animal protein content as compared with those quoted above from Orr's book, are believed to reproduce in the main the changes in our diet during the last two years.

Although we have used considerably more animals than did Dr. Chick and aimed at a stricter control of the other dietary factors that may affect growth, our finding that

wheatmeal bread from flour of 85% extraction and white bread from flour of 75% extraction—fortified in the manner described—do not differ markedly in nutritive value contrasts with Dr. Chick's statement that wholemeal flour of 82% extraction is superior to white flour of 73% extraction corrected for its deficiency of protein, minerals, and vitamin B₁.

A more refined statistical analysis than it is possible to give here somewhat weakens the apparent superiority of the white-flour diet in the first experiment and somewhat strengthens that of the wheatmeal diet in the second, but in both cases the difference between the two diets remains non-significant.

I should like to express my thanks to Dr. D. W. Kent-Jones and to Dr. Magnus Pyke for checking the thiochrome values of the diets used and for their advice and criticism; and to Mr. E. C. Fieller of Boots Ltd., Nottingham, for his statistical analyses of the data.

lesions each night. In the morning, with the ointment still on, the patient goes to the ultra-violet radiation department, where the ointment is removed by means of olive oil, a thin film of which is left on; then the ultra-violet irradiation is carried out. This treatment is given every day. At the same time the patient takes 1,000 units of vitamin B₁ by mouth daily. In some cases the ointment is so removed by movement in bed at night that it has to be reapplied in the morning before going to the radiation department. In other cases in which there are particularly thickened lesions I add 20 to 30 grains of salicylic acid to the tar ointment and advise the patient to scrub off the scales with a stiff brush or by the use of pumice stone. The ointment is reapplied after this exfoliating treatment, and then the radiation treatment is carried out as above. In certain cases I have used, in addition to the above measures, 300,000 units of vitamin D daily, but I have found that patients who have not had this have done just as well as those who have.

A word of warning must be given: care should be exercised in the treatment of children by this method, as the danger of lighting up a tuberculous focus is always present when general light baths are taken by young people.

Commentary

I have treated some 53 cases in this way. Admittedly the number is not large, but I have watched the condition gradually disappear in every case. Furthermore, the patients tell me from their own experience that they have never been so clear in the whole of their psoriatic life, and, incidentally, have never felt so well before. I am convinced there is a future for this method. The only drawback I can see is difficulty of daily attendance for radiation treatment. As, however, more and more large factories, etc., have increased facilities for their workers, including ultra-violet irradiation, something may yet evolve to overcome the loss of time at work. It is necessary to insist on daily ultra-violet irradiation, as the treatment will not produce the same results if it is given only once or twice a week. This I have proved.

A good many of the patients who received treatment and responded to it have had psoriasis for over 40 years, 30 years, 20 years, 16 years, and lesser periods. They had been constant in their attendance for treatment, and the measures which they had resisted included exfoliating salicylic and tar ointments, cignolin, etc., high-vitamin dietary, protein-shock therapy (T.A.B. vaccine, aolan, peptone, and whole blood), ultra-violet radiation, autogenous vaccines, oestrogenic substances, tar baths, x-ray therapy, and, in one instance, a course of gold therapy (using solganal B oleosum).

I cannot dogmatize on the prognosis of these cases, but from past experience it has been learnt that once a case of psoriasis has been completely cleared that case may remain clear for some considerable time. Should there be a recurrence the patient is warned to attend for treatment immediately, and the prospect is that the condition can be brought under control rapidly while it is still of small extent.

I know that psoriasis can clear for a time without treatment and with almost any treatment, but when it starts to clear in every resistant case dealt with as above I think the treatment must take the credit. Now that I have stated that so far no snags have been encountered I expect they will begin to arrive, but it is the universal response to the line of treatment which has caused me to write this short paper.

A TREATMENT FOR CHRONIC PSORIASIS

BY

ALLAN BIGHAM, M.D.

Honorary Dermatologist, Bradford-Royal Infirmary

The dermatologist, perhaps more than any of his medical colleagues, views with reserve sweeping claims on behalf of new treatments. The great variation in individual skin sensitivity impresses upon him the truth of the old adage, "One man's meat is another man's poison." Bearing this in mind, I can state that I have been amazed at the uniformity of response of chronic psoriasis to a line of treatment I have recently evolved. The two methods which I have partially combined are those of Madden (1940) and Goeckerman and O'Leary (1932). I will run through these briefly.

Madden's treatment resulted from a most comprehensive investigation of some 259 cases of psoriasis. He divided these into small groups and treated each group by a different method, utilizing the following: vitamin B₁, vitamin B₂, vitamin B whole complex, brewers' yeast, vitamin C, oestrogenic substances, sulphanilamide, bismuth salicylate in oil, anterior pituitary extract, adrenal cortex extract, low-fat diet with vitamin B₁, low-fat diet and liver extract, low-fat diet with vitamin B₁ and anterior pituitary extract, and low-fat diet with vitamin B₁, anterior pituitary extract, and adrenal cortex extract. He came to the conclusion that the best results were obtained with a low-fat diet plus 1,000 international units of vitamin B₁ daily by mouth, combined with an exfoliating ointment. Madden, however, says he realizes that not all cases will respond to this treatment. Goeckerman and O'Leary's line of treatment was as follows: the patient is anointed with a 2% ointment of crude coal tar before retiring at night. In the morning the ointment is removed with olive oil, leaving a thin film on the affected areas, and the body is then exposed to gradually increasing doses of ultra-violet light. In the interval between treatments a bland ointment, such as boric acid salve or petrolatum, should be applied.

Method of Treatment

My method has been as follows. The patient is told to rub 2% crude coal-tar ointment in soft paraffin into all

Medical Memoranda

Cysticercosis Epilepsy treated with Sulphathiazole

The recent articles by Blythe (*British Medical Journal*, 1941, 1, 401) and Ewing (*ibid.*, 1941, 2, 263) prompt me to record the following case under my care.

PREVIOUS HISTORY OF THE CASE

A man aged 29 was found unconscious in Sutton Park at 11.50 p.m. on June 29, 1941. He was taken to Sutton Coldfield Cottage Hospital, and transferred to Great Barr Park Colony the following day. He remembered leaving camp on June 29 at 4.30 p.m. and going to Birmingham, and nothing more. There was a slight smell of alcohol in his breath.

The personal history was as follows. No illness as a child. In 1930 he joined the Royal Navy and saw service in the Mediterranean, in 1932 in the Baltic, and in 1935 in China. In 1937 he returned to civilian life, where he worked in Bedfordshire, labouring until 1939. In 1939 he joined the Army and has served at home since.

In 1935, while serving in China, he suffered from "a tropical disease"; he did not know what it was and he is unable to remember the symptoms. Subsequent to this on seven occasions he has had an attack of loss of consciousness with complete amnesia of the incident. Since 1935 he has complained of headaches and mental depression. He has also noticed that on each occasion preceding his seizure the headaches have increased in severity and culminated in the fit. There was no history of vomiting or otorrhoea; he has never suffered from meningitis.

CONDITION ON ADMISSION

His I.Q. falls within normal limits; he is dull and somewhat apathetic. He sleeps quite a lot; often asks for some tablets to make him sleep, but he is asleep before the tablets can be procured. His memory on the whole is fairly good, but he is unable to give many details about himself. No family history of mental disease or of convulsions could be obtained.

Examination of Nervous System.—Pupils equal and responded to light and to accommodation, and ophthalmoscopic examination showed blurring of both disks on the nasal side: also venous pulsation on the right side. Nothing else abnormal found on examination of the cranial nerves. Upper extremity: Power and muscle tone normal and equal on both sides; reflexes average and equal on both sides; no sensory loss; joint sense and muscle sense normal; co-ordinated movements normal; no astereognosis. Abdominal reflexes were normal on the right side but diminished on the left. Lower extremity: Power and muscle tone appeared normal, with no perceptible difference on the two sides; no sensory loss; co-ordinated movements normal; joint sense and muscle sense normal; knee-jerks somewhat increased on both sides, especially the left; ankle-jerks increased, especially on the left side; plantar reflexes, right flexor, left extensor; ankle clonus not obtained; no Rombergism; sphincters normal.

General Examination.—Nothing abnormal found on clinical examination of the heart, lungs, and abdomen; no albuminuria; no glycosuria. Blood pressure: systolic 150, diastolic 88. Blood: Wassermann, negative; Kahn, negative; gonococcal fixation test, negative. Blood film, differential count of leucocytes: polymorphs-neutrophil 58%, eosinophils 6%; monocytes 19%, lymphocytes 17%. A slight increase of eosinophils and a marked increase in the monocytes.

Cerebrospinal Fluid.—Colourless and clear, definitely under increased pressure, degree not measured; cells, 2 per c.c.m.; protein, 35 mg. per 100 c.c.m.; chlorides, 720 mg. per 100 c.c.m.; reducing substance present; Lange gold curve, no change; Wassermann negative in all directions; direct film, no acid-fast bacilli or other organisms seen; culture, no growth.

X-ray Examination.—Head, thorax, and extremities were all radiographed for the presence of cysts. In the left lung there was a cyst about the size of a five-shilling piece, which showed

the features of a hydatid cyst. There was also a suggestion of an infected left maxillary antrum. Nothing else abnormal was found.

In view of these findings it was considered that the symptoms were due to the presence of a hydatid cyst of the brain.

TREATMENT ADOPTED

The report of a case reached me (verbally) of a hydatid cyst of the liver which, at operation, had secondarily infected the peritoneum and had been exposed to sulphonamide treatment (given primarily for a superimposed secondary infection). In this case it was found that the daughter cysts in the peritoneum were being discharged through the wound in a shrivelled condition, and, further, the percentage of sulphonamide in these daughter cysts was greater than that in the blood stream. The effect of chemotherapy was therefore tried in this case, the preparation used being sulphathiazole (M & B 760).

On July 9 the patient was given four tablets (2 grammes), and this was followed after six hours by two tablets (1 gramme) four-hourly for forty-eight hours. This in turn was followed by two tablets six-hourly for forty-eight hours, and the course was completed by giving two tablets three times a day for a further three days. At the end of the week (July 16) the man was re-examined. He was no longer complaining of headaches. There was no mental depression and he was no longer apathetic, nor did he sleep to an abnormal degree. There was a great change in his personality. He became bright and cheerful, and he took a natural interest in the comings and goings in the wards. His abdominal reflexes on the left side, which had been sluggish, reacted normally and equally with those on the right. His left plantar reflex, which had been extensor, now became flexor. His ankle-jerks and knee-jerks on the left side became equal with those on the right, but both remained rather more active than normal. Both disks showed blurring on the nasal side.

The findings were thought to be so promising that it was decided to repeat the course of sulphathiazole. On July 27 this was given as before, except that instead of terminating on the seventh day the course was continued until the twelfth day. On August 8 the patient was re-examined. The improvement had persisted, and the only abnormal findings were that the disks showed some blurring on the nasal side and the knee-jerks and ankle-jerks on both sides were still somewhat overactive. A differential leucocyte count was made: polymorphs—neutrophil 61%, eosinophils 0%; lymphocytes 34%, monocytes 5%. The monocytes had returned to a normal percentage. No eosinophils were formed. A further radiograph of the lungs was taken under conditions (kV, mA, time exposure, and distance) similar to the first picture. It was found that the cyst was less obvious than in the first picture; it was, however, still present. The size as depicted on the radiograph did not appear to be materially altered.

I fully realize that enough time has not elapsed since the treatment was started to allow any conclusions to be drawn. However, in view of the recent articles on cysticercosis epilepsy and the possibility of an approach to it by chemotherapy, I thought this case interesting enough to quote. I would be grateful for any comments.

I must thank Dr. D. M. Macmillan, medical superintendent of this Colony, for permission to publish this case, and also my colleagues for their advice and helpful criticism.

L. J. SEGAL, M.R.C.S., L.R.C.P.

Great Barr Park Colony, Birmingham.

Giant Hydrocele successfully treated by the Sclerosing Method

I have now treated seventy-four cases of hydrocele of the tunica vaginalis, some at the Injection Clinic at the Southend General Hospital and some in private practice, with complete success in every instance, although in about one-third of the cases more than one injection proved necessary in order to effect a complete cure. It takes on an average about three months for a hydrocele to be cured by this method.

The technique is simplicity itself; it consists in tapping the hydrocele and withdrawing all the contained fluid, and then

rather than a medical subject. A closer study convinces one of the value of its arguments to both combatant and medical officers. The first-aid section is adequate, laying stress on the problems of immediate treatment.

This is no book for the complacent—or perhaps it is. It is clear, concise, and deliberately realistic. It is well constructed and well written. As Tom Wintringham puts it in his introduction, this book can be recommended to every citizen "who can help to ensure that our wounded fighting men or civilians get what they deserve in the way of aid and comfort."

Notes on Books

Prof. J. B. S. HALDANE is a doughty controversialist, and his essays entitled *Science in Peace and War* (The Scientific Book Club, 111, Charing Cross Road, W.C.2) are frankly tendentious; naturally so since they first appeared in the defunct *Daily Worker*. Even in the chapter on human physiology the bad capitalist baron is revealed lurking behind the scenes waiting to injure the virtuous worker. People who are honest with themselves must recognize that emotion colours their views—witness the heightened appreciation of Soviet scientists in this country since last June. But it is unusual for a man of the intellectual ability of Prof. Haldane to see everything in such sharply contrasted tones of plain black and white. Each chapter is full of useful information and then ends with a Marxian moral. Interspersed with scientific facts we find such statements as that the classification of animals and plants was invented at the same time as the chronometer because both were needed for the purposes of imperialism (p. 90). But when he writes on page 209, "Our rulers [are] sabotaging the war effort . . . largely through sheer blind hatred of the workers," Prof. Haldane rules himself out of court.

Good Health on War-time Food, by BARBARA CALLOW, M.A., M.Sc. (Oxford University Press, 6d.), gives a short account in very simple language of what is meant by body-building foods, energy foods, and protective foods, and contains many practical hints for making the best use of the food available at the present time. It is evident that the author herself is tackling the problem with courage and real enjoyment, and her book should put fresh heart into numbers of housewives who are only too anxious to feed their families well but who do not always know just how to do it.

In his book *Diet in Sinus Infections and Colds* Dr. E. V. ULLMANN made a useful contribution to the study of the relationship between general disorders and local disturbances of the nasal mucous membrane, and argued effectively that laryngologists should pay more attention to diet when treating sinus troubles and recurrent nasal catarrh. Since the first edition appeared in 1933 there has been much wider recognition of the part played by dietary habits in building up resistance against infection, and as a result the surgical approach to sinus disease has declined in favour of more conservative methods that take into account habits of life, constitutional defects, a deficiency of vitamins, and other dietetic errors. In preparing a new edition (Macmillan and Co., 8s. 6d.) Dr. Ullmann has made some changes in the dietetic treatment recommended, but basically the book remains the same. He has added chapters on mother's milk, on allergy, and on vitamins, with special reference to vitamin A.

The *Bulletin of War Medicine*, under the auspices of the Medical Research Council, is edited by Sir H. Harold Scott and his colleagues at the Bureau of Hygiene and Tropical Diseases. The Index to Volume I (Nos. 1-6), 1940-1, of this valuable publication has now been issued at 6d. by H.M. Stationery Office.

Martin Croft, by JOSEPHINE BELL (Longmans, Green and Co., 8s. 6d.), is a straightforward novel of modern times with a largely medical background. The people and situations are clearly depicted and the writing is commendable. A warped and self-torturing medical man (apparently a hospital physician, but the

point is left obscure) gives his name to the title-page. He and his Victorian period-piece wife—a bad domestic tyrant—are shown against some more attractive human figures, including Dr. Croft's two medical housemates in the Harley Street area, and the girl who acts as secretary to all three doctors and holds the centre of the stage through most of the book. One of the secondary figures is a very nasty unqualified mental healer, who gets his deserts in the long run; there is also an attractive and virile young American with a gift for healing. The author is already known as a competent practitioner in the detective story line. This is a book in which criminal business plays a very subordinate part, the chief motive being the portrayal of character and temperament in the years just before the war, and it ends with the return of Dr. Croft, his outlook changed, from the beaches of Dunkirk.

Preparations and Appliances

A USEFUL SPECULUM

MR. JOHN STALLWORTHY, F.R.C.S., Oxford, writes:

The following very useful modification of Graves's vaginal speculum (Fig. 1) will commend itself widely to general practitioners as well as to those who specialize in gynaecology. The disadvantage often experienced with a metal speculum is the difficulty in obtaining illumination of the cervix and vault. This difficulty has been met by making the lower blade of the speculum of curviline. By this means an indirect illumina-

FIG. 1. (Patent No. 540,806.)

FIG. 2.

FIG. 3.

tion is provided. The power for the light can be obtained from dry cells, or from an electric main if a suitable transformer is used.

An extensive trial of this instrument has proved it to be most efficient. Although metal and curviline join together in the one instrument it can be sterilized by boiling without any dismantling. In place of the screw handle illustrated in the

photograph one fitted with a slot can be obtained. This is of advantage when the instrument is being used in a busy clinic.

Figs. 2 and 3 show the speculum in use, the latter being a photograph taken with the illumination provided by the instrument itself.

The new speculum is made by Vann Bros., Ltd., and can be obtained from them at 63, Weymouth Street, London, W.1.

A SINGLE OR BILATERAL BÖHLER BRAUN LEG SPLINT

Mr. R. BERTRAM BLAIR, M.B., F.R.C.S.Ed., surgeon to the Hull Royal Infirmary Fracture Clinic, and Dr. NORBERT KLEIN write :

We wish to introduce to those who are interested a simple kind of leg splint made after the Böhler Braun type.

try-outs and repeated alterations we produced a single leg splint which could readily be turned into a bilateral when found necessary. Our experience of air-raid casualties satisfied us that the effects of many "incidents" demanded the use of a bilateral leg splint, as many casualties arrive with fractures of both limbs.

It is claimed that the splint is practical, easily manufactured, and comparatively cheap. The material required is as follows:

- 8 ft. 14-in. red deal 8 in. wide by 5/8 in. thick
- 3 ft. red deal 5 in. wide by 5/8 in. thick
- 14 ft. bar iron 3/16 in. by 3/4 in.
- 8 ft. bar iron 1/2 in. by 3/16 in.
- 6 pulleys
- 2 dozen bolts and iron nuts
- 8 corner iron chips

The splint can be made in a hospital workshop at little cost, the material costing no more than 25s. Tarran Industries, Ltd.,

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

In our "blitzed area" it was soon found that the demand for the Böhler Braun was far greater than the supply. The shortage may have been due to the difficulty in obtaining the necessary labour, but probably more especially due to the lack of the raw material. In addition, the question of cost became an important factor. These considerations led to the idea of devising a simple, readily made splint. With the collaboration of the joiner at a base hospital a splint was made; and after

Hull, have made for us a more finished splint which would cost £2 15s.

The advantages of the splint are that it can be turned out in bulk at £2 15s.—that is to say, at half the cost of any such splint on the market; that it is transportable—when folded up it is parcelled into a space of approximately 33 x 12 x 5 in.

The photographs show the splint ready to be assembled, as a single unit, as a bilateral splint, and actually in use.

SATURDAY NOVEMBER 15 1941

NEW RULES FOR ASEPSIS

It has become abundantly clear in recent times that "hospital infection" is by no means a thing of the past. It must always have existed, although remaining mostly unrecognized, in "septic" wards, but it has now become a major problem in hospitals dealing extensively with casualties. The detailed study of wound flora, and in particular the typing of haemolytic streptococci, have made it possible to trace the spread of infection from case to case: that this is a frequent occurrence and may involve considerable numbers of patients was shown by the investigations of A. A. Miles and others published in this *Journal* last year. The burden of their argument was that the many precautions taken in the operating theatre do not always extend to ward work, where various faults in technique may cause avoidable wound infections. Few surgeons know everything that goes on in their wards, and many details connected with the sterilization of various materials and the care of wounds are left to the discretion of the nursing staff. It is with no disrespect to the nursing profession that some of their methods have been condemned, since they may reasonably ask that instructions for the proper conduct of such work should be made available; nor are they, in fact, by any means wholly responsible for the defects in technique which have been brought to light. There is need, in fact, for a thorough review of aseptic technique in the light of modern knowledge. So far as it concerns ward work, and as the direct outcome of recent research, this need has been met by the publication of *The Prevention of "Hospital Infection" of Wounds*, a memorandum sponsored by the War Wounds Committee of the Medical Research Council and the Committee of London Sector Pathologists. This furnishes in simple language full instructions for the conduct of dressings, the sterilization of all ward apparatus and materials, and other precautions necessary to safeguard wounds from extraneous infection. It should be widely studied, and may well serve as the basis for generally accepted hospital rules or, indeed, be adopted *in toto* for that purpose.

The chief instructions for avoiding contamination by dust and by droplet infection are already widely observed. Apart from the oiling of floors, it is laid down that sweeping and bed-making should be finished an hour before dressings are begun, and that during the dressing itself bedclothes should be moved gently. Closed plasters are a prolific source of dangerously infected dust, and should be opened only in a special room. A pattern is given for a simple and effective mask, and masking of the staff and silence on the part of other patients are enjoined during the conduct of dressings. The method of doing dressings requires two people, and may be considered too elaborate for

universal employment; on the other hand it is carefully thought out, and every step has its reason. The operator is not required to "scrub up," but merely to wash his hands; he works entirely with forceps, and should not touch the wound and the surrounding skin, the inner dressing, or any sterile material. It should be noted that this technique demands a generous supply of Forceps and certain utensils; a shortage in this direction is the most easily remedied source of difficulty and consequently of danger. Some may wish to vary these instructions, but if so they will do well to bear in mind their underlying principle: that the hand should never touch either the wound or anything supposed to be sterile. The observation of this single rule would perhaps do more than anything else to prevent avoidable wound infections. It is also pointed out that contamination of wounds may take place when they are handled by others than the ordinary surgical staff; precautions must therefore be taken when calling in the services of the radiologist, masseuse, or physiotherapist.

It is now notorious that infection has frequently been transmitted by utensils and other materials which are believed to have been sterilized but have not. Baths of various kinds have played a sinister part in this connexion: a full-sized bath must be treated chemically, and rubbing over with strong lysol is recommended. Arm baths must, if necessary, be treated in the same way, but it is far better to boil them; another strong injunction given is that every ward should possess a sterilizer of such a size that it can contain all bowls, dishes, and other such utensils which require sterilization. Heat is preferable to chemical disinfection whenever it is feasible, and full instructions are given for the proper use of the autoclave; four alternative methods are offered for the sterilization of syringes by heat. There is nevertheless an appendix on chemical disinfectants, dealing only with the three principal types of coal-tar origin, with instructions for their specific uses, and the suggestion that some such instructions should be posted up in every ward. The intelligent co-operation of the nursing staff in all these matters can be secured by teaching them elementary bacteriology from this point of view, preferably with simple practical demonstrations. It is finally suggested that a large hospital needs a senior officer whose chief business it is to supervise the control of infection, both by teaching and by seeing that these rules continue to be observed. We commend this memorandum very strongly to surgical staffs, with the suggestion that they either adopt its rules or make better ones if they can.

SCIATIC PAIN

Sciatica is not a clear-cut syndrome. The only constant symptom is pain, but from time to time and from patient to patient even this varies as much in its localization as in its severity. The pain may or may not be accompanied by scoliosis, muscle wasting, weakness, absence of the ankle-jerk, or a host of eponymous physical signs with a value in inverse ratio to their number. The most interesting feature of the condition known as sciatica is that nearly every one of the symptoms and signs is largely inexplicable at present.

Sciatic pain is distressingly common and very crippling. It has always been grouped in a class with the equally unexplained pains of lumbago and brachial neuritis. As with them, though there are many known causes of the pain, the greater number of cases have had to be termed "idiopathic." Unfortunately most of the known causes are serious and often fatal conditions. It must be remembered that a minority of the patients with sciatic pain will be suffering from neoplasms of the spinal cord or its coverings, or from invasive new growths in the region of the sciatic nerve itself. Happily this minority is very small, but it is large enough to demand full clinical, radiological, and pathological investigation of any patient with sciatica whose pain has lasted more than about three months, especially if the onset was gradual and if there are signs of impaired conductivity in the nerve or its branches. The recent interest shown on both sides of the Atlantic in prolapse of the nucleus pulposus of the intervertebral disk has thrown much light upon a small number of chronic and persistent cases.¹ But, as Barr and his colleagues² insist, this is a very rare lesion and one which a busy general practitioner is unlikely to meet with more than once in his lifetime. Kellgren³ has recently reported the discovery of fifteen cases of disk prolapse in as few as seventy cases of sciatica. This unduly high incidence must not be regarded as typical, however, and it could have occurred only in the unusual circumstances of a specialized neurosurgical or hospital research unit.

The big problem facing the general practitioner and the general physician lies in the vast majority of the patients in whom a diagnosis of "sciatica" is made. Their sciatic pains, for lack of better knowledge, have had to be labelled "neuritis," "inflammatory," or even "idiopathic." These patients account for at least nine-tenths of the sufferers from sciatica, and anything which will help to elucidate their symptoms will be of great value. Often enough an unsatisfactory diagnosis is the result of an inadequate physical examination, and the patient has been treated by placebos or by empirical physical measures directed towards the sciatic nerve itself. As James Cyriax has pointed out,⁴ the sciatic nerve is probably the most innocent of all the structures that may be causing the pain. What is needed is a thorough clinical examination to determine the site of the causative lesion, the nature of which still unfortunately eludes us. Cyriax⁵ clearly outlines how this should be done, basing his methods of clinical investigation upon the work of Sir Thomas Lewis⁶ and of J. H. Kellgren.⁷ These observers showed that the commonest explanation of "idiopathic" sciatica is that it is a referred pain arising from lesions of muscle, ligament, or fascia around the pelvis and lower lumbar spine. Such pain has been produced experimentally by Kellgren⁸ by injecting very small quantities of hypertonic saline into the erector and other muscles of the lumbar spine. What is perhaps even more important, he has relieved, and has even perma-

nently cured, some cases of sciatica and "neuritis" by injecting local anaesthetics into tender spots in these muscles. The introduction of the needle into the tender spots has reproduced the pain of which the patient complained, and the injection into that point and nowhere else has relieved it. Cyriax now gives us a detailed account of the way in which the site of these lesions may be determined. It is important to note that his clinical examination is detailed and thorough. Many will differ with him over the interpretation of the physical signs which he discusses, but no one can deny the importance of the fact that in this large group of patients the site of the causative lesion may usually be found with considerable accuracy.

The major problem remains. The diagnosis of the site of the lesion, accurately as it may be made and as accurately confirmed by the results of the injection of local anaesthetics, is only half the battle. For what, after all, is "myositis"? How, if at all, does it differ from "fibrositis"? How long will both these terms have to remain names entirely devoid of pathological significance? As each year passes the number of such names increases. "Panniculitis" and "perineuritis" are fairly well established though quite devoid of meaning in terms of morbid anatomy. Obviously the next step lies in the direction of pathology. In the meantime, we may be thankful for further help in the problem of anatomical diagnosis.

HYALURONIDASE

A process which may be of some importance in several acute infections and has hitherto been very imperfectly understood seems now to be undergoing rapid elucidation. The story goes back to the discovery by Duran-Reynals in 1929 of the "spreading factor" which has since been associated with his name; this was contained in a watery extract of testicle, and caused the widespread and rapid diffusion in the tissues of any particulate material injected with it, including micro-organisms, which consequently produced abnormally extensive lesions. It was shown by variations on this form of experiment that the only action of the spreading factor was to increase tissue permeability. Testicle is the only tissue containing it in considerable amount, but four years later Duran-Reynals showed that a substance having the same action is produced by certain bacteria. Its study from this point of view was then taken up by McLean, who had observed that in horses undergoing immunization the swelling produced by an injection of diphtheria toxin subsides slowly, whereas that produced by *Cl. welchii* toxin almost instantaneously disappears. A spreading factor is in fact produced by many bacteria which cause rapidly invasive infections—notably staphylococci, streptococci, pneumococci, and *Cl. welchii*—and it seems reasonable to conclude that invasiveness and the action of the spreading factor are connected. Substances with a similar action exist in some snake venoms, and can also be extracted from malignant tumours. Until quite recently their nature and mode of action were unknown, but these have been elucidated with surprising completeness by the observations and deductions of E. Chain and E. S. Duthie.⁹ These were made possible by the identification some years before by Meyer and others of hyaluronic acid as the substance to which vitreous humour and synovial fluid owe their

viscosity. Chain and Duthie showed that testicular and bacterial extracts which had the spreading effect also reduced the viscosity of a hyaluronic acid solution to that of water, the degree of both activities corresponding; by also demonstrating that a substance having the properties of hyaluronic acid exists in skin they linked the two phenomena, and made it appear certain that the increased tissue permeability which underlies the spreading effect is due to the breakdown of hyaluronic acid in the tissues. The enzyme responsible for this action they have named hyaluronidase, and it remains to be determined whether there is only one such substance, regardless of its origin, or whether the enzymes formed by bacteria and those found in testicle or snake venom differ in any of their properties. That there may be such differences appears likely from the recent work of K. Meyer and others,² who had previously noted discrepancies between hyaluronidase content and capacity for causing spreading. They now report that there is a difference in optimum pH for activity between extracts of testis and bacteria, and find also that extracts of many strains of haemolytic streptococci, though of high spreading activity, have little or no power to break down hyaluronic acid. Studies on these lines have brought to light an extraordinary feature in the behaviour of haemolytic streptococci. It is well known that in the first few hours of growth in a fresh medium these organisms sometimes form capsules which later disappear. This capsule is composed of a substance indistinguishable from hyaluronic acid, and it now appears that by subsequent production of hyaluronidase the organism brings about the dissolution of its own capsule. This phenomenon has recently been studied by D. McLean,⁴ who confirms the fact that in streptococci of Groups A and C capsule formation and hyaluronidase production are mutually exclusive. Pneumococci also produce hyaluronidase, but their capsules are not composed of hyaluronic acid and therefore persist, although pneumococcus hyaluronidase will destroy streptococcus capsule. McLean found also that the addition of hyaluronic acid to a culture medium for streptococci led not to increased capsulation but to greatly increased hyaluronidase production. It is quite possible that this process has an equivalent in tissues subject to rapid streptococcal invasion. It is at least probable in a broader sense that this enzyme plays an important part in acute inflammation, and its study should amplify our understanding of that process.

PECTIN AS A BLOOD SUBSTITUTE

The successful use of blood derivatives in the treatment of shock has demonstrated the necessity in such cases for replenishing the volume of circulating fluid with a fluid which has identical or similar physical characteristics. Blood derivatives are inevitably limited in amount and expensive to prepare. A substitute is highly desirable. Gum acacia was used for this purpose in the last war: it has the disadvantage that it is toxic and difficult to reprepare. Recently Taylor and Waters⁵ have proposed the use of isinglass or fish gelatin, and preliminary experiments have given satisfactory results. Pectin solution is now proposed by Drs. Hartman, Schelling, Harkins, and Brush⁶ as a possible alternative. Pectin may be described as a colloidal carbohydrate of a high molecular weight and rather complex composition. It is prepared from plant cells, where it is probably combined with cellulose. For

the purpose of the present investigation solutions were made from a commercial dry powder, great care being taken in sterilization and buffering of the final product. One-half per cent. of the pure pectin solution has about the same viscosity and osmotic pressure as whole blood. As with other colloidal solutions, every lot does not turn out alike, and every batch of pectin solution has to be tested against citrated blood and suspensions of red blood cells, including examination for haemolysis, rapid sedimentation, and preparation of film.

Experimental observations show that pectin is retained in the body for a short period, and is then eliminated rapidly in the urine. There is no obvious cumulative effect. Liver function as measured by the fractional bromsulphalein test and fibrinogen shows slight depression only with massive doses. Preliminary experiments on dogs and rabbits proved that pectin solutions were non-toxic and non-antigenic. The low blood-pressure level in dogs after haemorrhage was rectified by injections of pectin. Similar satisfactory results followed the treatment of dogs with experimental bile peritonitis. The observations made on human operative cases are, however, not convincing. Only four cases are quoted, and in only one of these was the blood pressure low before the pectin solution was given. Far more controlled proof of the clinical value of pectin solutions is needed before it is considered in any way as an alternative to blood derivatives in the treatment of shock.

X RAYS IN TREATMENT OF INFLAMMATIONS

A timely review by Pendergrass and Hodes⁷ of the x-ray treatment of inflammation opens with the statement that its value has been well recognized by radiologists from the beginning of the century, but that the majority of other physicians remain to be convinced of its benefits. This scepticism, they think, is in some measure due to a lack of well-controlled experimental evidence, and they accordingly devote part of their paper to a summary of recent work in this field. Although a bactericidal effect can be demonstrated with large amounts of radiation, it is agreed that the small doses in therapeutic use are unlikely to have a direct influence on bacterial morphology or physiology. A uniform and characteristic response to such small doses, however, is dilatation of the blood and lymph capillary vessels, so that the passive hyperaemia of an inflamed volume of tissue is transformed into a region of active hyperaemia, with speedier resolution as the result. The radiosensitivity of leucocytes is also such that even a small dose of radiation destroys a sufficient number to "decompress" the inflamed focus, and it can do this at an earlier stage in the process than can surgical incision and drainage, which usually awaits the localization of the infection in a definite abscess. These two effects are probably enough to account for the benefit given by radiotherapy in inflammatory conditions, though there may also be enhancement of the normal immunological responses and the setting free of protective antibodies.

A more important cause of scepticism is the natural suspicion with which a therapeutic agent is viewed when it is reported efficacious in a wide variety of conditions. But the two effects referred to above are a reasonable explanation not only of how radiations work but also of why they are of value in so many different diseases, for the basis of inflammation is the same, whether the disease is called parotitis, actinomycosis, whitlow, carbuncle, and so on. Pendergrass and Hodes report their results in many such conditions, and call a case successful only if it is

⁷ *Amer. J. Roentgen*, 1941, 45, 74.

relieved in a considerably shorter time than is usual when radiotherapy is not employed. On this basis the proportion of successful results in bursitis is 52%, in carbuncles 45%, in cellulitis 78%, in erysipelas 83%, in furuncles 72%, in acute post-operative parotitis 52%, and in warts 98%. These modest claims should inspire confidence, and when in addition their paper is supported by a bibliography of nearly 200 references, by no means confined to radiological literature, it is rather surprising that the scepticism referred to should persist. The treatment of septic fingers in the out-patient departments of our hospitals is seldom such as to merit congratulation, and any registrar or house-surgeon who is in the habit of referring such cases to the x-ray therapy department can testify not only to the shortening of the period of incapacity but also to the restoration of useful function in fingers which would otherwise have been amputated. At a time when every man-hour is of such importance, the attachment of radiotherapists to industrial centres where much time is lost through septic fingers and other minor inflammatory conditions would be of great value. The technique of radiotherapy in these conditions is simple, and the doses required are so small—Pendergrass and Hodes usually give 100 to 200 r daily for three to five days—that there is no risk of radiation injuries; thus with the present shortage of radiotherapists the hospital or armament works casualty officer could be taught the essentials in a few weeks. The radiotherapist interested in the treatment of inflammatory conditions has gained from experience the indications for varying the time intervals between successive doses and the size of such doses, but there is no reason to suppose that the casualty officer would be any less apt.

SCHISTOSOME DERMATITIS

Since Cort¹ described the occurrence of an acute dermatitis from penetration of the skin by the cercariae of a schistosome the subject has been intensively studied in America. The condition is common on the bathing beaches of Northern Michigan, Wisconsin, and Manitoba, but it also happens in Europe, and its occurrence in at least one place in the British Isles—Cardiff—has been reported by Matheson.² Cort described his own symptoms as a prickling sensation about ten minutes after immersion of his hand in water infested with the cercariae, followed quickly by urticarial blotches which subsided in about half an hour, leaving minute macules. In less than twenty-four hours intense itching developed, papules began to appear, and in two days the hand was swollen and painful and the papules became pustular. The condition began to subside in five days. Horny skin was not affected; the cercariae seemed to make their entry by the hair follicles. The disease naturally acquired by bathers follows a similar course, though pustular complications do not seem to be common unless the water is otherwise polluted; but sometimes the lesions have taken as long as three weeks to subside. Outside the experimental field, those who suffer have almost always been bathing or wading, so that the disease is popularly known as bather's or swimmer's or water itch. The cercaria first identified by Cort as causing the condition was *C. elvae* Miller. That occurring in Cardiff was *C. ocellata*, which appears to be the common schistosome in European outbreaks. Subsequent work in America has established that dermatitis may be caused by at least three others—namely, *C. douthitti*, *C. physellae*, and *C. stagnicolae*—and Cort suspects that most of the twenty-odd

cercariae of schistosomes which do not set up the systemic disease, schistosomiasis, may in man nevertheless be capable of causing dermatitis. The immediate hosts are water-snails: either *Lymnaeidae*, of which the species *Stagnicola emarginata angulata* (Sowerby) is the commonest in Michigan, while several others figure in Wisconsin; or *Physidae*, which, as Brackett³ has shown, also harbour cercariae in the latter State. The carrier snail at Cardiff was *Lymnaea stagnalis*. A particular species of cercaria is not entirely specific to any one variety of snail. Much less is known about the adult schistosomes and their hosts, but it is generally believed that they occur in water birds: it is suggested, for instance, that *C. physellae* may be the larval stage of *Pseudobilharziella querquedulae* of the blue-winged teal. One cercaria, *C. douthitti*, is known to be derived from a schistosome infesting mice, musk-rats, guinea-pigs, and rabbits, and certain experiments with it are interesting. It has been assumed that the violent cutaneous reaction of human beings to invasion by cercariae is a measure of their inability to penetrate beyond the skin. Brackett⁴ experimentally infected a young rhesus monkey with *C. douthitti* by almost daily immersions over a week, and found at necropsy four weeks after the first infection not the slightest trace of dissemination. In experiments on himself with *C. stagnicolae* and *C. elvae* he found no trace of the parasites in sectioned skin at twenty-nine and fifty hours after infection, but there was ample evidence of burrows, some of them blind, extending no further than the Malpighian layer. He concluded that these experiments confirmed the observed epidemiological fact that no case of systemic infection had ever been noted in the areas where bather's dermatitis is present. The possibility that one or other of these cercariae might assume the faculty of invading the human body, like *S. haematobium* or *mansoni* or *japonicum*, would indeed be alarming in view of their prevalence. A recent communication by Penner⁵ is therefore likely to lead to further examination of the subject. He immersed a healthy young rhesus monkey for an hour in water containing *C. douthitti*, estimated to number 28,000. At necropsy five and a half days later there was evidence of extensive but mild dermatitis. Migrating worms were plentiful in the lungs and slight haemorrhage was noted. He suggests that the same process might occur in man, and especially in young children, and that the migrant cercariae, even if they went no further, might carry other infections mechanically from the outside to the lungs and intervening tissues. Full details of his work are not yet available. It is possible that this unexpected finding was due to some exceptional feature of the experiment, out of the range of the circumstances associated with natural infection.

PICROTOXIN IN ANOTHER ASPECT

German textbooks on pharmacology of thirty years' ago had much to say on convulsive poisons such as picrotoxin. To a young English student at the time they seemed only to be stressing their lack of relation to useful therapeutics. Recently, however, convulsive poisons have found a use, and all who have tried it realize that picrotoxin is a certain weapon in the fight against an overdose of narcotic. Barbiturate coma, no matter how deep, can be dispelled by hourly intravenous injections of 10 mg. of picrotoxin, and it is likely that other forms of narcosis are equally tractable. This dose repeated in a normal person would be apt to

¹ *J. Amer. med. Ass.*, 1928, 90, 1027.

² *Trans. roy. Soc. trop. Med. Hyg.*, 1930, 23, 421.

⁴ *Ibid.*, 1940, 31 (Sec. D), 49.

⁵ *Arch. Derm. Syph.*, 1940, 42, 410.

⁶ *Science*, 1941, 53, 327.

produce convulsions, but after an overdosage of barbiturate it exerts an effect which is entirely beneficial. Unfortunately picrotoxin is no proprietary drug! it has no manufacturer's advertising power behind it, and so its value is still too little known.

The antagonism between picrotoxin and barbiturates can easily be demonstrated in animals.¹ If a group of mice are injected with a dose of nembutal which will kill 80% of them their lives can be saved if they are also injected with a dose of picrotoxin which by itself would kill 80% of them. Recently a paper by F. E. Rosenthal² has appeared which reminds us of another aspect of the physiological action of picrotoxin. Injected into normal rabbits it causes a fall of body temperature; this observation was made by Harnack so long ago as 1894. If the injection is given subcutaneously the dose must be very large (1.2 mg. per kg.); if, however, the injection is made vertically downwards through the brain to the neighbourhood of the hypothalamus, as a "para-infundibular" injection, then so small a dose as 1 microgramme of picrotoxin in 0.05 c.cm. of distilled water will cause a fall of 4.1° C. in four and a half hours. Now barbiturates given in large dose subcutaneously will also cause a fall in temperature; thus phenobarbitone (luminal) in a dose of 0.05 gramme per kg. caused a fall of 5° C. in a rabbit in five hours. This is, of course, a very large dose, corresponding to 45 grains for a man of 60 kg. If picrotoxin and phenobarbitone are given simultaneously the effect of the one is neutralized by the other and the body temperature remains normal. The same phenomenon is seen with picrotoxin and paraldehyde. As the cooling effect of picrotoxin is accompanied by bradycardia, and as it is a stimulant substance, its action is believed by Rosenthal to be due to stimulation of a cooling centre in the diencephalon closely related to the centres controlling the parasympathetic system. When phenobarbitone is given simultaneously the absence of temperature fall is thought to be due to narcosis of this cooling centre, and not to be related to the fact that phenobarbitone itself causes a fall of temperature. For other substances which can cause a fall of temperature act additively with picrotoxin. Thus calcium chloride, administered by a para-infundibular injection, and aconitine both act additively with picrotoxin in causing a fall of temperature.

Interesting observations can be made by injecting small doses of potent substances into the hypothalamic region. It is, however, unlikely that a precise analysis of their effects will be possible until new technical methods of studying the activity of the brain are developed.

PLAGUE IN SOUTHERN INDIA

Not so long ago, perhaps as a result of memories of the Middle Ages and of the Great Plague of London, it was commonly believed that plague was an urban disease which tended to spread from one city to another along the trade routes. This view accorded well with the discovery that rats of the black rat and to a less extent of the grey rat carried the disease to man. More recent observations, however, have shown that plague is often a rural infection carried on either as an enzootic or epizootic of wild animals whose association with man is as sporadic as it is accidental. Sylvatic plague is already well known in Manchuria, California, and South Africa, but hitherto its presence in India has been undetected. George and Timothy,³ however, have now brought forward evidence

which strongly suggests that sylvatic plague occurs in the Nilgiris in Southern India. The Nilgiris form a plateau in Madras Province roughly 1,000 square miles in extent, with an average altitude of 6,500 feet, though some of the peaks rise to over 8,000 feet. The climate is equable and temperate, the warmest months being only about 9° F. hotter than the coolest. Plague first attacked the district in 1903 and has been present ever since, a rough periodicity of three to four years being evident in maximum incidences. Previous observations by George and Webster⁴ have shown that sylvatic plague does not occur in the plains in Southern India, but in the hills the common occurrence of sporadic outbreaks of human and rodent plague, apart from the lines of communication, and the not infrequent appearance of pneumonic cases are features which are not unusual in those countries where the sylvatic type is known to exist. A preliminary survey of the rodent and flea population of the Nilgiris showed the presence, in addition to the black rat *Rattus rattus*, of a number of common animals, including what the authors refer to as a bandicoot, the mole rat *Gunomys kok*, the field mouse *Leggada booduga*, the bush rat *Golunda ellioti*, the "musk rat" *Pachyura caerulea* (really a shrew), and the house mouse *Mus musculus*. The flea fauna comprised *Xenopsylla cheopis*, *X. astia*, *X. brasiliensis*, *Ceratophyllus nilgiriensis*, *Stivalius* sp., *Leptopsylla musculi*, *Ctenocephalus* sp., and *Pulex irritans*; of these fleas *X. brasiliensis* was found naturally infected on a black rat, while experimental evidence shows that *Stivalius*, of which three subspecies are present in the area, and *Ceratophyllus nilgiriensis* are able to transmit plague from one mouse to another. The three *Xenopsylla* fleas are excellent vectors, while *Leptopsylla musculi* has been found by Chinese workers to transmit infection: as it bites man only with reluctance, however, it is probably not of great importance. Since the three species of *Xenopsylla* and also *C. nilgiriensis* were all found on mole rats, which have no close association with man, it is obvious that conditions for the existence of sylvatic plague are almost ideal. Actual proof of the presence of this form of plague must, however, await the discovery of infected fleas or infected rodents living entirely apart from man and his haunts.

At a recent meeting of the Council of the Royal Society of Medicine Sir Henry Dale, M.D., P.R.S., was presented with the Gold Medal of the Society, which is awarded triennially for valuable contributions to the science and art of medicine.

Surgeon Rear-Admiral G. Gordon-Taylor has arrived in Boston to attend the Clinical Congress of the American College of Surgeons as a representative of the Royal Navy and the Royal College of Surgeons of England.

The Canadian Medical Association Journal announces that the C.M.A. has set up a committee on industrial medicine under the chairmanship of Dr. J. G. Cunningham of Toronto. The purposes of the committee are to survey the situation and define the scope and objectives of industrial medicine; to consider the qualifications and training of physicians and nurses for service in this special branch; and to take stock of the personnel and training situation in Canada to-day, with a view to fuller prosecution of the war.

"PERFECT SIGHT WITHOUT GLASSES"

BY

A. SEYMOUR PHILPS, F.R.C.S.

Assistant Surgeon, Royal Westminster Ophthalmic Hospital

This attractive slogan, or some modification of it, makes its appearance every few years, and lately it has bobbed up again, this time in the programme of the B.B.C. Brains Trust. The public are recommended to read two books on the subject in which it is stated that perfect sight can be achieved by exercises (and one of the two insists on a diet as well) and without the aid of glasses. It can be said at once that neither of these books is to be taken seriously, and there is very little truth or sense in either. The purpose of this article is not to expose the tricks of ophthalmic quacks, but to state what can and what cannot be done by eye exercises.

What Exercises Cannot Do

No exercise has been devised which can make a large eye smaller or a small eye larger, or which can change the shape or refractive index of the eye in any permanent way. In other words, and it cannot be stated too clearly, exercises are not a substitute for glasses in long sight, short sight, or astigmatism. This is as much as to say that *no* exercise will replace glasses which are genuinely needed; but unfortunately there are many of us wearing glasses unnecessarily, for they are prescribed by practitioners having no medical knowledge. It is not surprising that exercises cure some people of wearing glasses which should not have been prescribed at all.

What Exercises Can Do: A. Convergence Insufficiency

To look at any near object requires an effort of convergence, and the nearer the object the greater the effort. In people who spend the day on such work it may be that the necessary effort cannot be sustained and one eye will then diverge. Binocular vision is thus broken, and diplopia results, which is interpreted by the individual as "blurring of the print." It is sometimes for this reason that one stops reading and covers the eyes for a few minutes, after which the rested internal recti can once more produce the necessary effort.

Now that the majority of the population are engaged on near work of some kind, cases of convergence insufficiency are not uncommon, and for these patients a course of suitable eye exercises is beneficial, and if the general health is sound a cure is likely to result. A holiday may also have the same effect.

To complain that the print is blurred is, in some quarters, as much as to ask for a pair of glasses. And another member will then have joined the host of wearers of unnecessary spectacles. Such a person will be a godsend to the curer of bad sight without glasses. A competent oculist would not have given him glasses in the first place, but would have put him on exercises from the start.

B. Heterophoria

A person with two good eyes working in complete harmony is said to have full binocular vision. The image he sees with the right eye is a little different from the image seen with the left, but these two images are fused into one complete picture, which thus has depth as well as height and breadth. This is stereoscopic vision.

On the other hand there is the person who has a squint. The images he sees are so dissimilar that no effort can fuse them into one stereoscopic whole, and he therefore uses one or other eye and suppresses the unwanted image—monocular vision.

In between these two types is the patient who has a heterophoria or latent squint. Here the desire for binocular vision keeps the eyes working together, provided that the general health is good and the eyes not tired. But when fatigued the eye muscles cannot summon up the effort required to sustain binocular vision, which therefore breaks down, and the eyes assume a position of rest, one eye squinting up, down, in, or out. His "hold" on binocular vision is not good and breaks down under a strain, and he momentarily becomes monocular.

The immediate effect of becoming monocular is to throw out one's judgment of distance, for the amount of convergence

required to see an object is a valuable guide to its distance from the observer. This is well demonstrated by covering one eye and trying to pour water at arm's length into a wineglass. If one eye is permanently lost other means of judging distance are called into play—for instance, the amount of accommodation required and the relative size of the object—and eventually such a person will readjust his values and once more become a good judge of distance. It is only when fatigue deprives one of binocular vision, on which one has always largely depended for judgment of distance, that any difficulty arises.

All this was perhaps of academic interest before flying became general, but it was then realized that some pilots, when learning to fly, were quite unable to land an aircraft with safety, and this although their visual acuity was up to standard; they could never tell whether they were going to land six feet up or hit the earth with a smack. The toll of aircraft so damaged became high and interest was aroused, and it was found that the majority of these young men had heterophoria.

Exercises will make many of these men first-class pilots, and to talk to them after such treatment is to be convinced. As one young man said who had been turned down for bad landing, "Now I can do a real 'daisy-cutter' every time." The development of this side of ophthalmology carries with it the names of Group Captain Livingston and Group Captain Clements, who were the pioneers of this work in the Royal Air Force, and whose study of heterophoria as it concerns flying is well known. While others are in a better position to make this statement than I, I believe that a man who has lost one eye while still young, and has had time to readjust himself, will make a perfectly safe civil pilot if the other eye is sound, but because of his restricted visual field is obviously unsafe as a Service pilot.

DIET IN PREGNANCY

BLAIR-BELL MEMORIAL LECTURE

The fourth William Blair-Bell Memorial Lecture was delivered at the Royal College of Obstetricians and Gynaecologists by Mr. W. C. W. NIXON on October 25. His subject was diet in pregnancy.

He discussed the effect of diet on health. In East Africa an interesting investigation was undertaken on two tribes, the Masai and Kikuyu, who have different dietetic habits. There were more bronchitis, tropical ulcer, and malaria among the Kikuyu, who largely ate cereals, than among the Masai, who lived on meat, milk, and raw blood. In Vienna during the last war there was starvation, and the death rate from tuberculosis was doubled in the period 1915-19. But in the province of Salzburg, where milk, butter, meat, and vegetables were still obtainable, there was little change. Again, in Germany the mortality from puerperal fever was almost doubled in twelve months as the result of the blockade. In this country it had been shown that boys from the elementary schools had poorer physique than those from the preparatory and public schools. Infectious diseases were much more serious among the children of the poor, and the incidence of dental caries was higher in the lower-income group of the population.

Deficiencies revealed by Pregnancy

He showed how the strain of pregnancy would reveal a borderline state of nutrition. Pregnancy was a "diet efficiency" test. Particularly did this apply to vitamin B₁. In Hong Kong he had seen Chinese women who early in pregnancy appeared quite normal, but later showed incipient beriberi with each additional month of pregnancy, eventually being brought into hospital *in extremis*. In some cases beriberi did not become obvious until a few days after delivery. It was the strain of labour that precipitated the condition of acute avitaminosis. Other deficiencies would reveal themselves in a pregnant woman more often than in her non-pregnant sister. This was well exemplified in Vienna in the last war, when night-blindness (due to vitamin A deficiency) developed first among the expectant mothers. Osteomalacia (Maxwell's disease) or adult

rickets resulted from the excessive drain upon the maternal calcium. It was probable that women in this country suffered from minor degrees of this disease in the form of pelvic outlet contraction. Increased demand for calcium by the mother was apparent from the dental caries which resulted from decalcification of the dentine and enamel. The foetal needs were greatest in the last trimester of pregnancy, and it was then that most of the tragic complications arose.

In 1938 McCance analysed the food eaten by 116 pregnant women of different economic levels. He found that the composition of the diet varied according to personal taste and income. The calorific value was 2,100 to 2,700 a day. Women in the poorer classes were shorter than the well-to-do. The haemoglobin level rose with income. Likewise, with a higher weekly wage there was an increased consumption of eggs, green vegetables, raw fruit, milk, brown bread, meat, and fish. In America and Holland there have been similar surveys with the special object of detecting vitamin B₁ deficiency. An investigation had been undertaken in London by the People's League of Health to consider the nutrition of expectant and nursing mothers in relation to maternal mortality and morbidity. Five thousand expectant mothers were investigated. One-half of them were given special tablets of vitamins and mineral salts. The report, shortly to be published, would be most illuminating.

The Technical Commission of the League of Nations had evaluated the physiological bases of nutrition. Nutrition experts (Mellanby, McCance, Orr) were agreed on the importance of milk and dairy produce, eggs, vegetables, fruit, and cod-liver oil during pregnancy.

There were several pregnancy states attributable to malnutrition. Wernicke's encephalopathy was a terminal phase of hyperemesis. Polyneuritis was not commonly seen in this country. In Hong Kong it was naturally more often met with owing to the marked deficiency of vitamin B₁ in the diet of the poor. In 1937 a series of 27 cases had been collected in the University clinic there. Vomiting was common to all patients in the early months of pregnancy. In habitual abortion doubt had been cast on the importance of vitamin E. Nutritional anaemia was all too common among the women attending ante-natal clinics in this country. Anaemia did have some slight influence on puerperal pyrexia. In a recent epidemic of puerperal sepsis, on analysis of the ante-natal notes, two cases had haemoglobin levels of 45% and 50% respectively two weeks before delivery. More haemoglobin estimations in ante-natal clinics would detect anaemia, and much ill-health in mother and child would be prevented. Osteomalacia had been put on the "nutritional map" by the classical researches of Preston Maxwell in Peking. It was one of the best examples of how pregnancy would reveal a malnutritional state. In puerperal sepsis Sir Edward Mellanby had shown there was a nutritional factor. He had reduced puerperal morbidity by giving pregnant women vitamin A.

Oedema, Toxaemia, and Avitaminosis B.

The triad—oedema, toxaemia, and avitaminosis B₁—had impressed itself on Mr. Nixon at an early stage of his career in Hong Kong. In 1936 he found that 10% of those delivered had had oedema in pregnancy at some time or other, lasting for more than seven days. Avitaminosis B₁ was a causative factor in many of them. Many pregnant women in this country noticed at different times swelling of the hands in the absence of toxaemia, anaemia, protein lack, and excessive salt intake. In collaboration with Dr. Margaret Wright of the research laboratories of Vitamins Ltd. fourteen of these oedematous cases had been examined. It was felt that some might be due to lack of vitamin B₁ in the diet, just as in the Hong Kong patients. Hyperemesis, hypertension, pre-eclampsia, and, of course, controls were also investigated from the vitamin B₁ aspect. Prof. Gordon King was now in charge of the Hong Kong University obstetric clinic. In the preface to his 1939 report he drew attention to the association of oedema, toxaemia, and avitaminosis B₁. His 1940 report had just arrived here. In studying this an interesting fact emerged. There had been an alarming increase in the number of eclampsia and beriberi cases. The severer the degree of eclampsia the higher the incidence of avitaminosis B₁, with concomitant increased mortality. An analysis of the eclampsia table was significant.

There were 42 cases, and 19 (45%) of these were complicated by avitaminosis B₁. Of the 13 fatal cases 11 also had this complication. Thus in 85% of eclampsia deaths there was the double lesion, eclampsia and avitaminosis B₁.

Dr. Margaret Wright and Mr. Nixon had collected 8 cases of eclampsia from different hospitals in this country, and had investigated their vitamin B₁ excretion. A statistical examination of the figures showed that in these the excretion of vitamin B₁ was significantly below that of the normal control pregnant women. Thus they had now proved that there was a positive correlation between eclampsia and a severely diminished vitamin B₁ excretion. The vitamin B₁ content of the placentae of the eclamptic patients was also significantly low compared with the normal. The placentae of 24 normal women had been examined, the average content of vitamin B₁ being 19 units per 100 grammes (average weight of placenta, 520 grammes). The placenta was a storehouse for vitamins. In the future it might be found that biochemical examination of the placenta would provide an indication of the state of nutrition of the mother and her offspring.

The assessment of nutrition was possible by simple clinical methods. A biochemical laboratory was not always to hand. A diet and economic questionnaire was of great assistance. The lower the income and the larger the family the less the food the mother would herself be taking. Stature was an indication of the dietary capacity of the community, provided hereditary factors were eliminated. Texture of hair, the nails, colour of mucous membranes, condition of skin, presence of petechiae, the teeth, gums, atrophy of the tongue papillae, sores at the angles of the mouth—all these could be rapidly observed. Follicular hyperkeratosis (vitamin A deficiency) was a special and early sign of improper feeding. In 1940 Pemberton estimated that of 3,000 children investigated in this country it was present in 5%. It was commonly seen in China, and responded with improvement of the diet and halibut-liver oil. Workers in Peking had noticed these skin changes due to vitamin A deficiency in the absence of ocular manifestations such as night-blindness and xerophthalmia. It was possible that in the coming winter we might find this evidence of vitamin A deficiency more widespread unless cod-liver oil were more universally administered in ante-natal clinics. Haemoglobin estimation would detect nutritional anaemia, and it should be done at the first visit to the clinic and be repeated at the thirty-sixth week.

Review of the Present Position

The rest of the lecture was devoted to a review of the present position. Mr. Nixon said:

Are pregnant women suffering from lack of essential food-stuffs? Will those of us who survive the next twenty years be able to point then to the adolescent with one or more nutritional stigmata and say he or she was a war baby? The survey of Sir John Orr before the war revealed the amount of malnutrition in this country. In present circumstances it hardly seems possible that there has been an amelioration of that nutritional state. Tuberculosis, a barometer of a community's nutrition, is on the increase. Many pregnant women are working long hours in factories where meals in canteens are far from ideal. At the end of the day how can they be expected to cook a health-giving meal? By interrogation of ante-natal mothers I find that the class of woman who is having difficulty in obtaining the proper kind of food is, regrettably, the soldier's wife with two or three children. The price of certain essential commodities, especially vegetables for making salads, is quite beyond her reach. Meat, eggs, milk, fruit, and cheese are restricted. Herrings, which should be eaten much more, are at times difficult to obtain. National wheatmeal bread is unobtainable in some districts.

If some of the expectant mothers are not getting the proper food should we resort to synthetic substances? It has been computed that in the U.S.A. 90 million dollars a year is spent on vitamin pills. Is it to be pills or food? The Nazis learned from an experiment in the Swiss Army. Soldiers were given vitamin C, iron, yeast, and gelatinous sugar. The results were poor. The German soldier gets his vitamins from butter, bread, yeast extract, soya bean, vegetables, and milk.

The produce from the land, if properly prepared and cooked, is more assimilable than the capsules from the laboratory. There is a psychological side to nutrition, as Pavlov has shown with his dogs. Let us hope we shall never live in a "brave new world" of Aldous Huxley with tabloid meals. We must make our obeisance to the biochemists and their epic researches, yet remind them of Ruskin. "What," he cried in a burst of righteous wrath, "what are we good for but to damage the spire, break down half the houses, and burn the library—and declare there is no God but chemistry."

Granted that malnutrition and poverty are twin sisters, entirely economic and therefore preventable, yet no one can gainsay the fact that vitamins are being thrown down the sink. The ignorance of many of our women in cooking food is appalling, and the apathy and obstinacy of their menfolk towards the subject almost universal. Dame Louise McLeroy's has been a voice crying in the wilderness: so often has she declared that the problem of maternal mortality and morbidity may be solved in the kitchen rather than in the laboratory. In war the fighting Forces require first consideration, yet it must never be forgotten that the pregnant and nursing mother is the next most important member of the community. Germany lost the last war on the home front—the kitchen front. Those of us who see to the welfare of expectant mothers have a heavy responsibility these days. Not only their fate but also that of the future generation is in our hands. We, as doctors, must interest ourselves more in the question, "Do they know how to buy, what to buy, and what to do with the food when they have bought it?" The worst type of obscurantism regarding diet is sometimes to be found among doctors and nurses. What exactly is the connotation of bland fluids, a light diet?

Three Lines of Attack

The problem of nutrition needs to be attacked on a broad front, and we in the medical profession have a big contribution to make; but we are lagging. In the belief that the health of the community in general and pregnant women in particular would be improved, I submit the following suggestions for your consideration:

1. *Maternity and Child Welfare Clinics.*—The supervision of diet should be one of the primary functions of all those working in maternity and child welfare clinics. These clinics are attended by a great number of women, who could be instructed in the art of buying and cooking food. The sum-total of hours spent and wasted by these women in waiting-rooms must amount to an astronomical figure. To lessen this monotony and at the same time benefit the health of the expectant mother I suggest that there should be in every waiting-room: (a) A milk bar attractively arranged, where a pint or more of milk should be given free. For those who do not like milk (and there are quite a number) varieties of "milk shakes" should be available. (b) A counter with salads, national wheatmeal bread, etc., daintily prepared—in fact, an Oslo meal. These should be distributed free or at minimum cost. (c) A demonstrator who would discuss with the women what best to buy at current prices with their limited means. She should demonstrate fully the preparation of dishes and talk over culinary problems in a simple, sympathetic, and practical way. She should act as an adviser, not teacher of the academic kind. If possible, communal feeding at the clinic would be ideal. Women of the poorer classes, particularly those of younger years, are only too willing to be educated in health matters when these are explained simply, and the benefits that accrue to them and their babies are emphasized by a doctor or nurse. It is for this reason I propose that the "food advice bureau" should be linked with the ante-natal and post-natal clinics. Thus by precept and example could the elementary principles of proper feeding be inculcated and the methods so demonstrated practised at home. In this way would the mothers of our country be guided so that they would themselves be contributing to one of the greatest measures in public health—proper nutrition. A start in this direction has been made at the Soho Hospital for Women. Through the good offices of Dr. B. S. Platt of the staff of the Medical Research Council I now have at my out-patient clinic an L.C.C. demonstrator who imparts to the waiting patients simple methods of preparing food for optimum health. The hospital provides all the materials necessary.

2. *Provision of Instruction for Doctors and Nurses in Dietetic Measures.*—There is an unfortunate and disappointing lag on the part of doctors and nurses in putting into practice the newer knowledge of nutrition. An awakening of a food conscience is necessary. Their opportunities for spreading the food gospel are unique, and yet many lay people are in advance of them in this respect. In their hospital instruction more practical dietetics should be included. For those who have graduated, short courses could now be arranged and practical hints published in the medical press. As nearly 60% of the women of England and Wales are confined by midwives it follows that these nurses are in a particularly good position to give dietetic instruction to their patients. The Central Midwives Board could assist in this direction.

3. *The Improvement of Diet in Hospitals and Institutions.*—Hospitals are lamentably behind in the provision of proper diet. Good food is ruined in the kitchen. The matron and the probationer, the steward and the wardmaid, the medical officers—all must develop an awareness of the transcendent importance of the kitchen front and take practical steps to ensure proper feeding not only of their patients but also of themselves. A proper perspective of preventive medicine—social medicine in contradistinction to curative—needs to be inculcated. Good health and good feeding cannot be divorced, and the marriage between midwifery and housewifery is long overdue.

CO-ORDINATION OF HOSPITAL ADMINISTRATORS

While public authorities and the governing bodies of voluntary hospitals are in conference on matters of hospital policy, plans have also been laid for the setting up of a single professional association of lay hospital administrators to give a lead both nationally and in the regions on all matters touching the recruitment and training of hospital administrators, their work and responsibilities, and to make recommendations to regional and national hospital councils on administration and management.

The Incorporated Association of Hospital Officers, founded in 1902, has hitherto restricted its membership to the administrative staffs of voluntary hospitals. The Incorporated Association of Clerks and Stewards of Mental Hospitals, founded in 1904, is representative of lay administrative officers of mental hospitals. These are the only two organizations restricting their membership and professional qualifications to lay hospital administrators, and their councils have decided to recommend to the members the adoption of an agreement for fusion under which at the same time provision will be made for the admission of stewards and other administrative officers of hospitals managed by public health committees of local authorities, Departments of State, such as the Department of Health for Scotland, and other analogous bodies. It is proposed that, for the time being, the educational work of the two bodies should continue on the present lines, but that a special committee should be set up at an early date to consider the problem of recruitment and training of hospital administrative staff in all its aspects. The committee will have in mind the recommendations in the Sankey and Hadow reports, as well as the results of the work of such bodies as the American College of Hospital Administrators.

Co-ordination of hospital services on a regional basis cutting across the old divisions between public and voluntary institutions will call for a certain uniformity in methods of business administration and a common system of accounts. It is hoped that the reconstituted association embracing lay administrators of all types of hospital will do valuable work in solving problems which will arise in the development of a satisfactory administrative system for all hospitals. As the principles and practice of management develop towards uniformity in all types of hospital there can no longer be room for entirely independent qualifications for lay administrators in the different sections of the hospital service. The united association will work out a system of recruitment and training which, while common to all, will allow for some degree of specialization by means of alternative examination papers.

POLISH MEDICAL FACULTY AT EDINBURGH

ADDRESS BY THE DEAN, PROF. JURASZ

The recent foundation of the Polish Medical Faculty within the University of Edinburgh was the subject of an address given by the Dean of the Faculty, Prof. A. T. Jurasz, at a meeting of the History of Medicine Section of the Royal Society of Medicine on November 5. Dr. J. F. Halls Dally, president of the Section, was in the chair.

Prof. Jurasz, who spoke excellent English, began by describing the Hitlerian war on Polish culture. From the University of Cracow 180 professors and others were sent to a concentration camp in November, 1939. A like fate befell representatives of the University of Poznan, and later of Lwow and Warsaw. Some eminent men of science had been sentenced to death; libraries had been closed and the contents confiscated; others had been reopened to serve the cause of the Germanization of Poland. Everything of special value had been taken from the museums and other collections and sent to Germany. Cathedrals and churches had been robbed of their treasures. Even German professors of distinction who had formerly been guests at scientific congresses in Poland had taken an active part in this plunder. This systematic and premeditated looting after hostilities had ceased had brought to the Polish nation a loss not smaller than that represented by the aerial and artillery bombardment of Warsaw. Buildings connected with education had been requisitioned. The Ministry of Public Instruction was occupied by the Gestapo, Warsaw University housed the security police, and secondary schools were taken over by the army.

A Scottish Welcome

In July, 1940, Prof. Jurasz continued, the remnant of the Polish Army, which included many doctors, was brought to the British Isles. In view of the presence of many Poles in Scotland Colonel Irvine Fortescue, D.D.M.S., Scottish Command, sought to organize a means of occupying and refreshing the minds of the medical men among them. He consulted Prof. F. A. E. Crew, who was commanding a military hospital with the rank of Lieut.-Colonel, and he arranged for batches of twenty Polish medical officers at a time to be attached to that hospital for periods of a fortnight. Further arrangements were made with the Medical Faculty of Edinburgh University and with the managing board of the Royal Infirmary whereby Polish medical officers might be spread among different departments and clinics. Linguistic difficulties, however, prevented these well-intentioned schemes from fully serving their purpose.

Finding that among the Polish medical officers in Scotland were many who had held academic positions in the Polish universities and that among the troops there were many students of medicine whose studies had been interrupted by the war, Colonel Crew made the further suggestion that these professors be given facilities at Edinburgh to teach their own people in their own language, and that the undergraduates should be allowed to complete their curriculum and proceed to graduation. These suggestions were gratefully accepted by the Director of the Medical Services of the Polish Forces in Scotland and by the Polish military authorities in London, who agreed to permit medical officers of academic standing to work in Edinburgh, and students to go up for refresher courses of from three to six months, and thereafter graduate, and return to the Army as reinforcements for the medical services.

The consent of General Sikorski, commander-in-chief of the Polish Army, was obtained, and the idea was embraced with enthusiasm by M. Cot, Minister of the Interior, who saw in it a closer cultural link between the Polish and British peoples.

The Beginnings of the Faculty

In October of last year, Prof. Jurasz said, he was instructed to go to Edinburgh and make contact with the University authorities. Prof. Sydney Smith placed before the Medical Faculty the proposal that a Polish Medical School be formed, and this received unanimous approval. In the Senate the proposal had the powerful support of Sir Thomas Holland,

the Principal, and was approved. The heads of the departments of the Medical Faculty placed their resources at the services of their Polish colleagues, and the Board of Management of the Royal Infirmary agreed to open their lecture theatres and wards to Polish professors, lecturers, and students, and more recently accommodation in municipal hospitals had also been placed at their disposal. The secretary of the University and the legal adviser to the Polish Government worked out the constitution of the new School, and drew up an agreement which was signed on February 24. The head of the School was the Dean. The teaching staff comprised six professors, seven lecturers, and ten other specialists. Edinburgh professors represented in the Faculty subjects for which no Polish lecturers were available. The curriculum and standards of teaching and examination were the same as those required in the Medical Faculties of Polish Universities. The programme of teaching was somewhat different from the British, but was according to Polish law. The examinations were practical, theoretical, and oral, and the chairman of the Examinations Board was the Dean. The Faculty comprised the Dean and seven Polish and nine British members, the latter being professors of Edinburgh University.

The inauguration took place in March last in the presence of the President of the Republic (M. Raczewicz). To those who participated, said Prof. Jurasz, it was one of their proudest moments since leaving Poland. They felt that a great responsibility had been entrusted to them, that they had the confidence of the authorities of the University of Edinburgh and held in their keeping the faith of Polish youth.

A Polish Hospital

A Polish hospital, named after Paderewski, had been organized in the grounds of the Western General Hospital. It had been equipped with generous help from America and was intended for the treatment of Polish civil as well as military cases. It was staffed by members of the Polish Medical Faculty and contained 80 beds and an out-patient department. Surgical beds in the Western General Hospital had been placed at the disposal of the Poles, as well as the use of operating theatre and x-ray department.

The School began with 77 students, 47 of whom were serving in the Forces. Some 30 had finished their studies in Poland but had not passed their examinations, and a refresher course was arranged for them. Prof. Sydney Smith and Prof. T. J. Mackie had kindly undertaken the examination of the students in forensic medicine and bacteriology respectively. For the second academic year, which had just started, there were 120 students, of whom five were Czechs. The first student to receive his diploma, M.B., B.Ch., at the hands of the Dean of the Faculty was Lieut.-Pilot K. Bazarnik of the Polish Air Force, who returned immediately to his fighter squadron.

Prof. Jurasz concluded by affirming the determination to maintain the high standard of Polish learning and by paying a tribute to their Scottish colleagues, from whom they had received every possible support and facility. The Polish Medical Faculty was an effective post in the front line of the fight against a destructive barbarism which had sought to impose its own perverted culture upon Europe. It was also a reaffirmation of the international ideal of learning and science.

The lecture was followed by a reception at the Polish Embassy in Portland Place. Among the British guests welcomed there by the Ambassador were Sir Henry Dale, President of the Royal Society; Sir Charles Wilson, President of the Royal College of Physicians of London; Sir Alfred Webb-Johnson, President of the Royal College of Surgeons of England; Sir Edward Mellanby, Secretary of the Medical Research Council; Mr. E. Rock Carling, Senior Surgeon, Westminster Hospital; Dr. H. E. A. Boldero, Dean of the Middlesex Hospital Medical School; and Capt. G. S. Elliston, M.P.

J. Bonaba, J. R. Marcos, and M. de Agorio (*Arch. de Pediatr. del Uruguay*, 1941, 12, 317) record four cases of encephalitis complicating pneumonia in children aged from 3 to 13 years. The encephalitis was indicated in the first case by aphasia, in the second by convulsions and coma, in the third by an extrapyramidal syndrome, and in the fourth by an ataxo-cerebellar syndrome. All made a complete and permanent recovery.

MALARIA ILLUSTRATED BY CINEMATOGRAPH FILM

The value of the cinematograph film as a means of conveying instruction in hygiene and health precaution was never better shown than in a sound film entitled "Malaria" which has been produced for world-wide distribution by the Shell Film Unit in collaboration with the Ross Institute of Tropical Medicine. With this film, which takes about half an hour to pass through the projector, the scientific critic can find no fault (except, perhaps, that the title refers to "microphotography" when "photomicrography" is meant—rather an important distinction now that microphotography has suddenly come into such wide use), and the lay spectator gains a great deal of information which is essential and even life-saving if his travels should take him to the malaria regions. Some of the photography was done at Horton Hospital, Epsom, in the malaria unit there, and some, particularly that dealing with methods of control, has been done in tropical lands. The first part of the film, which includes an interesting flash of Sir Ronald Ross at work with his microscope, illustrates, mostly by clever cartoon, the life cycle of the parasite. The way in which the malaria germ attacks and destroys the red blood corpuscles is vividly shown. The second part concerns the carrier, and compresses into a few minutes the two or three weeks which elapse between the laying of the eggs, through the larval and chrysalid stages, and the emergence of the adult mosquito. Nothing could be better than the "shots" illustrating the mosquito actually laying its eggs or its method of taking its blood meal.

Control of Mosquitoes

The third part of the film deals with mosquito control. The importance of such control is suggested by rapid pictures of great engineering works, such as Singapore docks, which have been made possible only by the most resolute measures to suppress the mosquito. But the point is brought home that malaria control can only be successful, whatever method is employed, if the co-operation of every member of the community in the malarial region is enlisted. The most important methods of stopping the larvae are shown to be by draining the land where mosquitoes breed, by spraying the surface of the water with oil, or blowing on to it a poisonous dust such as Paris green. To destroy or keep away the adult insect, spraying, mosquito-proofing, and the use of mosquito nets are advocated, and all these are shown in action. Control in the long run resolves itself into careful choice of healthy sites for houses in mosquito-ridden countries, taking suitable measures against breeding grounds, and personal protection against the adult insect. The technique of the film and the imagination shown in the choice and use of material deserve high praise. It is being issued for instructional purposes to H.M. Forces.

Local News

IRELAND

Health of Eire

The public health of Eire as reflected in the statistics for infectious diseases for the year 1939-40 continues to improve, the total of 6,146 notifications—roughly 1,900 fewer than in the previous year—being the lowest recorded since 1950. The incidence of diphtheria, which in 1938-9 (2,983 cases) was disappointingly high, was lower in 1939-40 than it had been for some years, the figure being 2,097. This is attributed in the Health Department's report to the immunization campaign which is being actively pursued, but regret is expressed "that the unfortunate dispute with the medical profession regarding fees for immunization . . . is still unsettled and consequently many children are still unprotected." The report records, however, that many practitioners "to their credit are carrying out the work without fee or reward." There were increases in the incidence of both typhoid and influenza pneumonia, that of typhoid being attributed to a serious outbreak in County Kerry in the summer months. Mortality from the principal infectious diseases declined notably during the year; the aggregate figure

of 385 deaths was the lowest yet recorded; in 1936 these deaths numbered 687. Although the total number of tuberculosis patients treated in 1939 was 18,521, or 443 more than in 1938, the number of cases under observation showed a decline of 1,057. Deaths from all forms of tuberculosis numbered 3,304, a rate of 1.13 per 1,000, as against a decennial average of 1.23. Both maternal and infant mortality compared favourably with the figures for the preceding year and those for the decennial period 1929-38.

SCOTLAND

New Blood Transfusion Plant for Scotland

The Government have agreed to make a grant to Scottish Blood Transfusion Services towards the establishment of two centres in Scotland for the processing of plasma taken from blood supplied by voluntary blood donors for use in hospitals. To each centre will be attached a whole-time mobile blood-withdrawal team, so that the services of country donors will be more readily utilizable than has hitherto been the case. One centre is to be under the direction of Prof. James P. Todd; the other, directed by Dr. C. P. Stewart, is also to be equipped with up-to-date plant for the preparation of dried plasma. While scientists in Scotland have done much useful work in the study of blood transfusion, they have not hitherto had the opportunity of developing the drying of plasma, the only drying plants in existence being attached to centres in England. The plant will be utilized not only in the preparation of plasma but also in experimental work. As dried plasma is believed to have better keeping qualities than liquid plasma, especially under difficult temperature conditions, it will now be possible to keep much larger stores of plasma available for Scottish civilian hospitals and for the Forces without risk of wastage, and adequate supplies will be ready for immediate use in bombarded areas. The services of Scottish blood donors were placed at the full disposal of the Forces at the outbreak of war, and it is hoped that by the establishment of these new centres the help given in this direction may be greatly increased. The address of the Scottish National Blood Transfusion Association is 10, Duke Street, Edinburgh, 1.

Cleanliness of Glasgow School Children

The first year of war, which saw the evacuation of school children from the large cities, the return of many of them, the closing of schools and dislocation of education, and the slow re-establishment of a modified regime, must stand by itself so far as statistics of medical inspection of school children are concerned; it can offer no useful comparison with previous years. The report, just issued, of the education health service in Glasgow during the year ended July, 1940, does, however, suggest that the improvement in the physical condition of school children which has been built up in recent years has been maintained. Measurements were taken between September, 1940, and April, 1941, of between 6,000 and 7,000 boys and a similar number of girls at 5 and at 13 years of age, and on comparing the measurements with those for 1939 a distinct improvement is shown, though, admittedly, the figures are not a true reflection of school population. The main attention of the school medical staff in Glasgow has been devoted to scabies, which has been increasingly prevalent; to pediculosis capitis, which was the most frequent cause of complaint against evacuated children; and to enuresis, which was greatly on the increase in 1940. It is admitted that as regards nits and vermin of the head the children evacuated from Glasgow were not as free as they should have been. The trouble is that so little can be done with the child whose head is not kept clean. A child may be cleansed, but hair cannot be cut without the parents' permission, and cleansing without cutting takes time. It is suggested that an attempt might be made to impose as a condition of attendance at school shorter hair styles for children; also that powers should be extended to allow examination of the person and clothing of the school child in the home. Enuresis was also the subject of widespread complaint from the reception areas at the first evacuation. Subsequently the presence of this defect was admitted in about 3% of the children examined. The school service has obtained good results by a combination of parental co-operation and gradually increasing doses of tincture of belladonna.

Correspondence

Radiographs and Pelvic Disproportion

SIR.—The leading article on "Radiology to the Help of Obstetrics" (p. 551) and the article by Mr. J. V. O'Sullivan on "radiographs and disproportion" (p. 543) in your issue of October 18 raise the very interesting question—the place that should be assigned to radiography as a guide to treatment in cases of pelvic disproportion. In their enthusiasm for this wonderful aid to diagnosis a number of obstetricians would have us believe that all is now simplified, and that from films of maternal pelvis and foetal head plotted out with exactness, as can now be done, the treatment is obvious. Such obstetricians are a menace to expectant mothers. There is a large number of cases in which from radiographs, no matter how perfect, you cannot tell whether the head will or will not pass, just as there are the other two groups: (a) cases in which the head can certainly pass (normal pelvis); (b) cases in which the head can certainly not pass (markedly abnormal pelvis).

Unfortunately there are three conditions which cannot be determined by x rays or any other means beforehand; and they are the most important factors of labour in minor pelvic disproportion: (1) the adjustment of head to pelvis which occurs as the lower segment develops and under strain of "labour pains"; (2) the give of the pelvis, which increases very markedly in the "premonitory" stage of labour; (3) the strength of the uterine contractions. Referring to "trial labour," here is what Chassar Moir wrote recently (*Edinb. med. J.*, 1941, 48, 361): "I do not intend to enter into a discussion of this topic: it is, however, not unfair to say that extensive use of trial labour amounts to an admission of inability to foretell the probable course of events in individual cases. There is little doubt that the main cause of this uncertainty lies in the difficulty in obtaining accurate measurements, and, secondly, of understanding the significance of the observed variations of pelvic size and structure." DeLee states in the 1940 *Year Book of Obstetrics and Gynecology*: "Since the x ray cannot measure the strength of the pains, or the moldability of the head, or the expansibility of the pelvis joints, or the nutation of the sacrum, or the rigidity of the soft parts, or the nervous mechanism of labour, or the metabolism of a parturient, etc.—you can see what a small role it plays in the routine conduct of a delivery; but I would not do without it" (p. 38). "The x-ray—even in stereo form—is not a perfect guide for the conduct of labour; we must watch it, but we can learn many things, and I would not do without it" (p. 42).

The procedure should be: (1) pelvic mensuration; (2) radiography of pelvis; (3) estimate of relative size of head and pelvis by hands. By these means cases can be segregated into: (a) those in which spontaneous delivery (with possibly assistance with forceps at outlet) is certain because of the good formation of pelvis; (b) those in which Caesarean section is necessary because of pronounced deformity; (c) those on borderline in which there is uncertainty, and consequently the 'trial of labour' is necessary—there is a large number of such cases.

In these borderline cases the trial of labour is necessary to complete the diagnosis as to whether the head will or will not pass—in other words, whether the labour should be allowed to proceed or Caesarean section should be employed. Here, as Thoms and O'Sullivan claim, a lateral radiograph is helpful. By observing large numbers of cases the obstetrician gains such knowledge that comparatively early in labour he can make a fairly correct surmise as to whether or not the head will pass. In a few cases, however, he may have to let the labour proceed into the "second stage," but a prolonged second stage should not be permitted, because of the danger to the child.

Cases of breech presentation at full term where the pelvis shows by x rays a minor degree of disproportion should be treated by Caesarean section; it is inadvisable to perform prophylactic version in order to test the relative size of head and pelvis.—I am, etc.,

J. M. MUNRO KERR.

Canterbury, Nov. 1.

Increase of Tuberculosis

SIR.—Prof. Lyle Cummins (November 1, p. 632) has suggested that the rise in incidence and death rate from tuberculosis observed in this country since 1939 is to be explained entirely by the discharge from sanatoria of "a great many tuberculous persons" at the outbreak of the war. I am not aware of the actual number so discharged, but it can hardly have been more than one-half of the total number undergoing institutional treatment for tuberculosis. The total number of tuberculosis beds in England and Wales at the end of 1937 was approximately 33,000.

The number of new cases of tuberculosis notified annually in England and Wales is in the region of 60,000 (tuberculosis of respiratory organs about 45,000). On the usually accepted view that the average duration of the disease is about five years, we must conclude that the total number of notified cases "at large" in England and Wales at the outbreak of the war was not much smaller than 300,000, and this takes no account of the unknown number of undiagnosed and therefore unnotified cases.

It is not easy to believe that the dispersal of about 16,000 cases among a population which already harboured more than 300,000 cases would so increase the amount of tuberculous infection in the community as to account for the rise in incidence and mortality observed during the present war. The theory becomes still less acceptable when we remember that the number of sources of infection outside institutional control in normal times is so great that practically every member of the community has been infected with tuberculosis by the time middle life has been reached. This continues to be so, notwithstanding the steady decline in tuberculosis mortality in this country during the present century, a decline interrupted only by the two great European wars. Little is gained by attempts to simplify what is in fact a complex problem, but if we are to concentrate our attention on a single one of the many factors involved let it be something more practicable and promising than suggestions for the incarceration of every possible source of infection.

During the war of 1914-18 there was a striking increase in tuberculosis mortality in all European countries engaged in the war or affected by its blockade, and study of this phenomenon has produced ample evidence of the importance of the nutritional factor. The case of Denmark provides the most convincing evidence. In Denmark tuberculosis mortality rose steadily during 1915 and 1916, but fell sharply in 1917 and continued to decline afterwards. Faber has shown how closely these changes coincided with the deterioration in the Danish food situation up to 1916 and improvement from 1917 onwards. In Britain tuberculosis mortality fell sharply in 1918. The highest mortality rise occurred in Germany, and though this began to fall from 1919 to 1921 it rose again from 1921 to 1923 during the period of economic distress and inflation. These are only a few of the facts which emphasize the importance of the nutritional factor. Other factors are certainly involved, perhaps not least increased hours of work and increased strain among the adolescent, but there is little evidence for the belief that changes in the infection factor are of great importance.

The use of such rhetorical phrases as "a bomb thrown among the public" is out of place in a scientific journal, and over-emphasis of one of the minor aspects of the problem can only result in distracting attention from vitally important aspects.—I am, etc.,

A. L. JACOBS, M.R.C.P.

London, E.1, Nov. 1.

SIR.—Dr. A. H. Bartley (October 25, p. 594) calls attention to the danger arising from tuberculous individuals with T.B. sputum, and asks for more rigid control. May I suggest that the best remedy would be careful education of every such patient in the precautions taught in a well-managed sanatorium? The danger from cases of open pulmonary tuberculosis is conditional, and can in most cases be prevented by such precautions.

Although not now in active practice I was concerned in the management of tuberculous cases for nearly thirty years, and found ample evidence that there is very little danger of the

spread of tuberculous illness if the usual rules are observed. Unfortunately many patients are insufficiently trained, or become careless after leaving a sanatorium, and this is a weak spot which always needs attention. Dragooning would not succeed in this country; but systematic education followed by tactful supervision is invaluable. It would occupy too much space to give the evidence for my statements, but they are supported by the records of Papworth and of some of our best sanatoria.—I am, etc.,

Farnham, Oct. 30.

F. R. WALTERS.

Fats and Carbohydrate Metabolism

SIR.—Your report of Dr. R. B. Lawrence's presidential address before the Section of Therapeutics and Pharmacology of the Royal Society of Medicine on carbohydrate and fat metabolism (October 25, p. 591) is provocative of many questions, because the great interest of the facts disclosed requires of us an attempt at interpretation.

The facts are apparently that in diabetes: (1) ketone bodies are burned (a word implying use and not storage) in the peripheral tissues; (2) ketone (ketonaemia) is harmful when it appears suddenly; (3) the precursors of the ketone bodies in the blood can, at least on occasion, be derived from depot supplies as distinct from diet; (4) the sequestration of fats in depots, as distinct, presumably, from their burning in peripheral tissues, can be increased by the deficiency of certain protein fragments in the diet (especially choline); (5) when the precursors of ketone bodies are depot supplies the metabolic pattern through which they pass may run parallel with hyperglycaemia—an event which, we have come to consider, is linked with the pattern of pituitary influence.

The first obvious question is this—If ketone bodies are burned in peripheral tissues, is this necessarily harmful to those tissues? If not, are we faced with a failure of the peripheral tissues to metabolize ketones when ketonaemia is associated with ketonuria and the toxic effects ascribed to ketosis? Are we to understand that insulin facilitates the burning of ketone bodies in the peripheral tissues and that this contributes not to their pathology but to their physiology?

The next question concerns the occasional correlation of lipaemia and hyperglycaemia. The implication here is that the lipaemia is derived from the pituitary metabolic pattern. Since this is here associated with inability to store fat subcutaneously, can this be the opposite pole of the process which produces pituitary obesity? How does this connect with the fact that in the experimental animal choline does not prevent the deposition of fat in the liver when injections of anterior pituitary extract have been given?

Is there not a contradiction in supposing, on the one hand, that hyperglycaemia facilitates lipaemia without subcutaneous deposition of fat, and, on the other, that it produces the subcutaneous deposits of diabetic obesity?

Whilst I appreciate the dangers of speculation in science, I feel that an ignorant man may at least help himself by asking obvious questions—that is, if he can get anyone to reply to him.—I am, etc.,

Coventry, Oct. 27.

K. E. BARLOW, M.R.C.S., L.R.C.P.

Vitamin-E Therapy in Neuromuscular Disorders

SIR.—The leading article on vitamin-E therapy in neuromuscular disorders (November 1, p. 618) is an excellent example of careful and unbiased criticism, in which the evidence for and against the proposed method of treatment, as well as the underlying physiological and pathological phenomena, are summarized, weighed, and evaluated. The conclusion reached is one with which few would wish to quarrel, in so far as it states that you find nothing yet to persuade you that "any disturbance of . . . locomotion in man is due to deficiency of vitamin E or is alleviated by treatment with it." This conclusion is based upon, and justified by, the evidence summarized in the article, but you have, I suggest, unfortunately gone beyond your brief in extending it and writing actually as follows: "We find nothing yet to persuade us that any human disease, or any disturbance of child-bearing or locomotion in man, is due to deficiency of vitamin E or is alleviated by treat-

ment with it." This statement can only mean that the treatment of habitual abortion with vitamin E also has no evidence to support it.

One welcomes all indications that the organ of scepticism is actively secreting, but one cannot be quite so pleased at signs of marked hypertrophy, accompanied, as so often, by an inability to distinguish simple conclusions even in the light of logic. Some two years ago you published a paper by myself (*British Medical Journal*, 1941, 1, 890) in which the records of cases of habitual abortion treated with wheat-germ oil or concentrates were summarized and compared with Malpas's figures, analysed by him to establish the chances of full-term pregnancy for untreated women who have aborted two, three, four, or more times (*J. Obstet. Gynaec. Brit. Emp.*, 1938, 45, 932). There can be no doubt about the figures. Malpas's analysis of 2,000 untreated cases shows that the expected number of full-term deliveries from forty-two women who have aborted four times or more is three; that number of treated abortions showed thirty-three successful full-term deliveries. The odds against this being due to chance were found to be about 10^4 to 1. One would have thought that such astronomical odds might have carried some kind of conviction even to the hypertrophic sceptic.

Apart from the forty-two cases mentioned above, there were fifty others that had had between two and four consecutive spontaneous abortions: here again the differences between the number of pregnancies experienced and the number expected in the absence of treatment were highly significant. From these figures there is to be drawn an obvious conclusion, which should surely be accepted provisionally, if only on the principle of Occam's razor. This conclusion is that the treatment was responsible for the differences between actual live birth rate and the rates expected on the basis of Malpas's analysis. The only other conceivable explanation is that Vogt-Möller's two series of cases, investigated in Copenhagen some years apart, and the cases treated by Watson and Tew several thousands of miles away in Canada, were all alike influenced in a favourable direction by some unknown and unsuspected cause rather than by the vitamin-E therapy to which these patients had been submitted, the only known common respect in which they differed from Malpas's untreated cases. This, surely, would be too much of a coincidence even for a critic of normal scepticism.

I submit, therefore, that the adventitious and irrelevant introduction of your leader writer's reference to child-bearing has no justification.—I am, etc.,

Treatment of Hallux Valgus in Soldiers

SIR.—May I crave space to make some comments on Lieut.-Colonel R. Brooke's article on the treatment of hallux valgus deformity in soldiers (November 1, p. 605). It contains important points which may be summarized as follows: (1) The patients are young males with only slight deformity. (They would not be in the Army if it were severe.) (2) Palliative treatment should be the method of choice. (3) If operation be necessary minimal procedures are best.

There are, however, certain other aspects which need to be considered, for on them depends the success or failure of treatment. Hallux valgus *per se* is merely part of a deformity-complex or general derangement of the fore-foot, and is the direct result of the pull of the adductor and other muscles on the great toe owing to spreading or fanning of the metatarsals. This spreading can be seen in all x-ray photographs, though it may not be marked in the slight cases, and involves only the first metatarsal. The metatarsal exostosis is due to intermittent pressure of the boot. I have yet to see a "bunion" not associated with alterations of the first metatarsal axis.

The metatarsal spreading is due comparatively infrequently to "toxic" causes such as rheumatoid and gonococcal arthritis. The much more common cause is hypermobility, instability, or incompetence of the first metatarsal. There is no space to enter fully into this matter. Sufficient to say that it is discussed in the publications of D. J. Morton, Lambrinudi, Girdlestone, and myself. I am at present preparing a cine film co-ordinating and amplifying the various observations.

Consequently the ideal treatment must include some correction of the position of the first metatarsal, and Lieut.-Colonel Brooke's suggestion of fixing the extensor hallucis longus to the inner side is of value. Undoubtedly the majority of the younger males require nothing further than excision of the metatarsal exostosis, and very many females even with an apparently bad metatarsal spread are perfectly satisfied without an arthroplasty of the metatarsophalangeal joint. I cannot agree that all arthroplasties end with flail toes, nor that it is impossible to correct the valgus deformity by this means. I have serial x-ray photographs showing that after removal of the proximal half of the proximal phalanx the actual correction of the position of the great toe equals the theoretical one. It is, of course, essential that any arthroplasty should not consist of removal of the head of the first metatarsal, because its removal destroys the supporting effect and merely exaggerates the incompetence of the bone. After an efficient arthroplasty there is a flail toe for some weeks, but if the operation be performed correctly voluntary control returns and is quite effective.

There will always be stiffness if the following points are ignored. It is essential to remove half the proximal phalanx, and in the younger members of the community (approximately those under 35) where new bone formation is fairly profuse the interposition of fascia by one of several methods is essential. In the older patients this fascial interposition is not required.

Finally, there is no essential difference between the civilian and the soldier. It is incorrect to say that good functional recovery is impossible in the case of the soldier. There is a much too common belief that in the majority of cases recovery is complete in a few weeks. Anybody who has followed up the series of these cases knows that recovery is by no means complete until the expiration of six months; that the period in which the patient returns to work, whether civil or military, depends on the type of work, and is shorter for the lighter forms of work and longer for the heavier. The rate of recovery and the degree of recovery depend far more on the care and skill of the operator and on the after-treatment than on the type of operation performed. It is common for the after-treatment to consist of early movements, but in view of the fact that in an arthroplasty we desire to obtain movement, that movement is restricted by the formation of excessive scar tissue, and that minimum scar tissue demands complete fixation in the early stages, I have always maintained that the correct after-treatment for at least three weeks is complete fixation in plaster-of-Paris. The best position to immobilize the toe is in about 20 degrees of dorsiflexion, because when we walk, and particularly when wearing boots, there is always a certain amount of dorsiflexion owing to the height of the heel. When the plaster is removed physiotherapy is of great value. Another reason for applying plaster-of-Paris is so that the metatarsal arch can be remoulded and held corrected through the early convalescent period.

I feel confident that attention to these points will alter Lieut.-Colonel Brooke's opinions on the results of operative treatment in soldiers as well as in civilians.—I am, etc.,

Manchester, Nov. 4.

W. SAYLE CREER.

SIR.—The article by Lieut.-Colonel R. Brooke deals with a problem of special importance at the present time. All are agreed that this condition, so amenable to treatment in peacetime, presents many difficulties now. The association of flat-foot with hallux valgus is almost a constant one, and it may be that treatment is not being sufficiently comprehensive to deal with this. A course of flat-foot exercises, as indicated by Lieut.-Colonel Brooke, should form the basis of treatment, and the exercises themselves ought to become almost instinctive. Many people go through life with quite symptomless flat-foot and hallux valgus. The increased strain of Army life and the wearing of Army boots by such individuals will often precipitate bunion formation and consequent breakdown in the foot mechanics. The boot, therefore, is not to be regarded as blameless. The soldier cannot discard his footwear, but much may be done to adapt it to the new conditions. The hard leather which overlies the bunion can be softened and stretched, or an inlet of soft leather substituted, so as to relieve pressure over the tender area. At the same time an ordinary football bar, placed behind the tread, will do much to relieve the strain on an irritable first metatarsophalangeal joint.

Where conservative measures fail radical operation is preferable to a soft-tissue reconstruction. Hallux valgus has an insidious onset, and many years may elapse before the patient is seen. This means that the cartilage on the head of the first metatarsal, where the original normal articulation took place, has degenerated. At operation it is seen to be thinned, eroded, or, in the later cases, to be frankly arthritic with osteophyte formation. Except in the earliest cases, therefore, any operation which replaces the first phalanx on this abnormal cartilage must be disposed to ultimate failure. Removal of the proximal half of the proximal phalanx, with excision of the exostosis on the metatarsal head (Keller's operation), will give the most satisfactory end-results. At least half of the phalanx should be cleanly excised, and the tendon of the extensor hallucis longus tenotomized well away from the wound to avoid adherence in the scar. The wearing of a pad of cotton-wool between the great and second toes should be insisted upon for at least six weeks.

Lieut.-Colonel Brooke's assertion that after this type of operation the valgus deformity persists is not borne out by my own experience, nor does the toe become a useless appendage. The return of function, indeed, is often remarkable. If care be the keynote of treatment in this complex condition there seems no adequate reason why the majority of patients should not return to their former duty.—I am, etc.,

Southport, Nov. 5.

R. S. GARDEN, F.R.C.S.Ed.

Diagnosis of Early Venereal Disease

SIR.—May I be allowed to endorse the importance of Dr. Noel F. Rowstron's letter (November 1, p. 632).

I agree that sulphonamides should never be administered to the patient who is about to visit a V.D. specialist for diagnosis. The diagnosis of venereal diseases must always be supported by pathological tests. The venereologist finds the gonococcus evasive enough without having it first of all doped by sulphonamides. Dr. Rowstron's remarks on the early diagnosis of genital sores are also very true.

The triad of the "venereologist's nightmare" is, in my opinion: (1) the "clinical" gonorrhoea, treated with sulphonamides; (2) the "cured" case, who has received no tests of cure; (3) the undiagnosed genital sore, previously treated with antiseptics.—I am, etc.,

Nov. 3.

C. HAMILTON WILKIE, M.D.,
Director of V.D. Services, Leicester.

Future of Mental Health

SIR.—Dr. Karin Stephen (October 25, p. 589) would appear to look to something called "psychotherapy" as the predestined cure for, and preventive of, all the mental and moral troubles of our present age. Formerly the great guardians of the *mens sana* were supposed to be our churches and our schools, and it is to be remembered that these institutions are still carrying on, although often—like the schools of "psychotherapy" themselves—sadly distracted by internecine feuds.

In short, no "theory" of mental and spiritual health has yet found anything like general acceptance in our distracted Western world, and under these circumstances it seems idle to discuss the setting up here and now of any official or semi-official organization to deal with the matter. Let none of our enthusiastic "post-war planners" take it upon themselves to propose the institution of a new "ministry" for which "candidates" have to be selected, examined, and "licensed" to deal with the "souls" of their fellow-countrymen. We doctors at least certainly do not yet know enough to arrogate to ourselves any such function. Let us rather go on individually studying the subject of mental stability and imbalance, and discussing our experiences in such papers as the *B.M.J.* Perhaps in the end some finally unchallengeable findings will be arrived at; then we can begin to talk of "organization," statutory or academic.

Towards this goal may I, as one who had much experience of so-called "shell shock" in the last war and regrets not being similarly employed in the present one, offer just a single contribution—a hint as to "how not to do it."

Any nervous or quasi-mental patient who is definitely curable and yet who is not getting better "of himself" needs in the

first place definitely individual treatment. This emphatically precludes the would-be psychotherapist from taking on a large number of cases simultaneously. Secondly—a perhaps even more important point—the patient must be treated in a mentally healthy milieu. In other words, on account of the strong effect of suggestibility, he must so far as possible live among sane people, who will be an example and encouragement to him. Such patients should obviously under no circumstances—so long as their ultimate cure is considered a possibility—be herded together among a lot of definitely insane people. Hence no institution which, for other reasons, is forced to deal with its inmates *en masse* is justified in calling itself a "mental hospital." Although many such institutions to-day include a considerable amount of hospitalization, they are primarily concerned with the care and maintenance of the incurably insane. Therefore the name "hospitals" should not be applied to them: it also gives the public a false idea of their essential function, which in the long run will be found bad policy.

There is much wisdom in what Dr. Karin Stephen says, particularly in her reservations. Yes indeed: *Quis custodiet ipsos custodes?* Who is to train the trainers of the trainees?—I am, etc.,

Duness, Sutherland, Oct. 30.

A. J. BRÖCK.

Loss of Vision following Haemorrhage

SIR.—The article by Dr. H. L. Tidy (May 24, p. 774) is full of interest. Quite a number of years ago I saw a few cases sometimes with loss of vision in one or both eyes. It followed haematemesis, haemoptysis, or post-partum haemorrhage, but never a traumatic haemorrhage. In the last war, now sometimes called the "first German war," I never heard of a case in Egypt during four years. The cases I saw in civil life never recovered. Elaborate investigation failed to throw any light on the cause. In the anaemias I have seen disturbance of the optic disk but never the total loss of vision which follows the haemorrhages referred to. So far as I am aware it remains an unsolved problem. Fortunately it is very rare.—I am, etc.,

Melbourne, Sept. 9.

JAMES W. BARRETT.

Nasal Snuffs

SIR.—With reference to the article on antiseptic snuffs by Dr. M. E. Delafield, Dr. Edith Straker, and Prof. W. W. C. Topley (February 1, p. 145), although confirmation of the results of using antiseptic snuffs for nasal infection does not seem available in South African research institutions at present, there can be little question of the benefit obtained by the local application of sulphanilamide derivatives to certain infective conditions of the nose in Natal, provided the drug is used as a dry powder in small enough doses to produce a comfortably clear condition without destroying nasopharyngeal protection. This suggests that inhalation of the dry powder would be effective in cases of pneumonia and save the large quantities at present prescribed orally for these patients. Moderation would be essential to avoid irritation of the bronchial tubes, though the immediate destruction of the infective organisms *in situ* might well be expected to give relief by carefully regulated application of the powder to all portions of the respiratory organs, including the nasal cavity.—I am, etc.,

Durban, S.A., Sept. 25.

F. GORDON CAWSTON, M.D. Cantab.

Industrial Medical Boards for Women

SIR.—Thousands of young women are joining munition factories, leaving their jobs and taking up work of national importance; thousands more are wanted, but the response to appeals and entreaties is not satisfactory. I suggest that one of the causes of the present reluctance to join is the fact that no attempt whatever is being made to grade the girls as to their physical suitability for the work they are taking up. As there is no medical examination we may find girls suffering from tuberculosis working and freely mixing in canteens and hostels with others; verminous girls infecting their more fastidious sisters; girls unfit for heavy work put to manipulate heavy machines. I have had some experience in examining and grading girls in the distributive industry, where the work is not

too strenuous, and even then my colleagues and I have found a number of girls unsuitable, on medical grounds, for the work. It is obvious there must be many more in heavy industry.

I would plead for the immediate institution of nation-wide medical boards, similar to the medical boards in the Army, to examine and grade women for work in industry. A lot of wasted effort in training girls who could be classified as unsuitable on medical grounds alone would be avoided, more suitable labour could be chosen, and absenteeism materially reduced. The expense of these examinations would be well repaid by the weeding out of infectious and unfit people, who could and should be referred to their doctors, medical officers of health, or hospitals. We would thus do a great work of preventive and curative medicine and use a unique opportunity to improve the health of the future mothers of the nation.

Needless to say that medical supervision should be continued in factory and workshop the adjustments be made, as the strain of industry will make itself felt.—I am, etc.,

London W.1, Nov. 3.

E. M. HERBERT.

A Municipal Hospital

SIR.—In view of the numerous statements concerning municipal hospitals which have recently been made and reiterated in the correspondence columns of the *Journal*, we consider it desirable that the following facts regarding the particular hospital which we serve should be put on record.

1. The medical superintendent does not seek to exercise his authority over the clinical work of the staff but rather to encourage their independence and initiative.

2. The senior clinical staff are men of high qualifications and attainments, and continuity of tenure is assured to them.

3. The members of the senior clinical staff devote the whole of their time and energies to the care of their patients in the hospital, and they are constantly available to guide and instruct the junior staff in the performance of the duties entrusted to them.

4. By liberal grants of study leave the Middlesex County Council encourages the clinical staff to visit medical and surgical centres at home and abroad. Until the outbreak of war full advantage was taken of these opportunities.

5. A medical society, which includes all the staff of the six general hospitals controlled by the Council, provides in its clinical meetings, held in each hospital in turn, a fruitful field for discussion and mutual criticism.

If these admirable conditions can be created in one group of hospitals under a county council they can be achieved by all. Where they exist "atmosphere" can be left to look after itself.—We are, etc.,

L. I. M. CASTLEDEN.

J. L. HAMILTON-PATERSON.

D. B. CRAIG.

G. H. JENNINGS.

J. N. DEACON.

R. M. MILLEN.

F. FORTY.

E. AD I. ROSSER.

Redhill County Hospital, Edware, Middlesex, Nov. 3.

Students and the Curriculum

SIR.—Mr. J. L. Taylor's letter (November 1, p. 629) would doubtless interest all those who are interested in the student's point of view. May I, through the courtesy of your columns, show that we Scottish students have not been idle in putting forward our views?

In each of the four universities discussions are to be held on the topic of medical education. It is probable that these will be along the same general lines as Mr. Taylor indicated. Each medical school will draw up its own report based on these discussions and on the discussions of the Medical Faculty Committee, and it will then be forwarded to the Scottish National Union of Students' Medical Bureau, which will draw up the final draft of the report.

There are many problems peculiar to the Scottish schools, and we hope that our efforts will enable us to ferret them out and draw them up in concise and presentable manner. We are only too well aware of the responsibilities which complete reservation from National Service places upon us, and are no less eager than our English fellow-students to play our part in the crises of to-day and the castles of to-morrow. This year has seen much closer co-operation between the respective

English and Scottish students to the benefit of both. I have every confidence that this is only the beginning of a long period of close and beneficial relations.—I am, etc.,

Glasgow, Nov. 2.

ROY MCL. ARCHIBALD,
Interim Convener, S.N.U.S. Medical Bureau.

Air-raid Shock

SIR,—We have had "railway spine," "traumatic neurasthenia," "nervous shock," "shell shock," and "bomb shock," and now Dr. W. E. R. Mons (November 1, p. 625) gives us "air-raid shock." May I protest against this latest addition to a mischievous and medically meaningless series?—I am, etc.,

WILLIAM A. BREND.

Neurological Clinic, Ministry of Pensions, Nov. 3.

Obituary

W. A. WETHERLEY-MEIN, F.R.C.P.Ed., F.R.C.S.Ed.

By the death on October 29 of William Archibald Wetherley-Mein at the early age of 52 Bournemouth and district has lost a skilled professional colleague and a generous and most kindly friend.

He was born in India in 1889 and educated at George Heriot's School, Edinburgh, the Edinburgh Dental Hospital, and the Royal College of Surgeons, Edinburgh, gaining the qualifications L.D.S. in 1916, L.R.C.S., L.R.C.P.Ed. 1917, F.R.C.S.Ed. 1920, M.R.C.P.Ed. 1925, and being elected in 1931 F.R.C.P.Ed. After practising dentistry for a very short time he gave this up and devoted his life to the practice of surgery, in which he was actively engaged at the time of his death. During the 1914-18 war he was surgeon lieutenant R.N. until he was invalided out of the Service. Later he became temporary lieutenant, R.A.M.C., and remained in the corps until the end of the war. Subsequently he held appointments as R.S.O. at Ancoats Hospital, Manchester, orthopaedic surgeon at the Bangour Hospital, and honorary assistant surgeon at the Portsmouth Royal Hospital.

In 1920 he came to Bournemouth, where he became honorary surgeon to the Cornelia and East Dorset Hospital, and to the Victoria Cripples' Home at Westbourne. He was also consulting surgeon to the hospitals at Milford-on-Sea, Shaftesbury, and Blandford. He was surgical specialist to the National Union of Teachers, and surgical specialist to the Ministry of Pensions for the Bournemouth, Poole, and district area. His work brought him into contact with a wide circle of friends, who will mourn his passing and will remember him for his staunch character and the loyalty and generosity of his friendship.

Wetherley-Mein was a keen yachtsman and sportsman, in which capacity were seen both his determination and strength of character, as well as his attractive sense of humour. In his busy life he still sometimes found time for sport, and it was while shooting only a few weeks ago that he was first taken seriously ill. In Freemasonry he attained the rank of P.P.G. Superintendent of Works for the Province of Dorset, and well merited the esteem in which he was held by all who knew him. He had been a member of the British Medical Association for twenty-four years, and when the Association met at Bournemouth in 1934 he served as honorary secretary of the Section of Pediatrics. He published a number of papers, principally on thermomy and electrosurgery, in which he had for long been particularly interested. At the time of his death he was engaged in writing a book on this subject. He was also president of the Poole Medical Society.

The loss of Archie Mein (as we all knew him) will for long be keenly felt by his many friends, colleagues, and patients. For his widow and his son, also in the medical profession, sincere sympathy is felt by all of them.

J. A. W.

W. DOUGLAS MACFARLANE, M.B., Ch.B., F.R.C.S.Ed.

We regret to note the death of Mr. W. Douglas MacFarlane of Glasgow, which occurred in Aberdeen on October 15. Mr. MacFarlane had been taken suddenly ill while engaged in examinations of nurses, and was removed to a nursing home, where he died. He had resumed his work only in the last four months, after a long illness of about fourteen months. It was characteristic of him that he went energetically into his usual professional duties, perhaps against the advice of some of his friends, who did not think that his cardiac condition would permit him to carry on his full work, but he always maintained that he would much rather die in full harness than in only a part of his ordinary professional activities.

William Douglas MacFarlane was born in Glasgow, the son of a well-known general practitioner in the East End of that city. He was educated at Glasgow High School, and graduated M.B., Ch.B. of the University in 1922. In 1926 he was admitted to the Fellowship of the Royal Faculty of Physicians and Surgeons, Glasgow, and in 1934 he became a Fellow of the Royal College of Surgeons, Edinburgh. From the beginning of his professional career he was determined to devote himself to surgery, and he joined the out-patient staff of the Western Infirmary, and later was assistant surgeon to the Victoria Infirmary. He concentrated, however, on the surgery of children, and was appointed visiting surgeon to the Royal Hospital for Sick Children, Glasgow, and clinical lecturer on surgical diseases of children. He became recognized as an authority on the surgery of children, and was a very keen operator and worker in his hospital. At medical society meetings he frequently exhibited coloured films showing operations in progress. About 1935 he was appointed consulting surgeon to the Clackmannan County Hospital, Alloa, an institution where he had considerable opportunity of doing urgent surgery, as many road and mining accidents were admitted. He was an associate member of the British Orthopaedic Association and a Fellow of the Association of Surgeons.

Mr. MacFarlane interested himself in medical journalism in Glasgow, and for a considerable number of years was secretary to the Glasgow and West of Scotland Medical Association, which controls and owns the *Glasgow Medical Journal*. The committee of that journal very gladly recognized his enthusiastic work on its behalf. Mr. MacFarlane was only 45 years of age, and was unmarried. Much sympathy is felt with the members of his family, two of whom are on hospital staffs in Glasgow, and a third is serving as a dentist in the R.A.F.

F. C. MARTLEY, M.D., F.R.C.P.I.

Those who have attended almost any Annual Representative Meeting of the British Medical Association during the last twenty years will learn with regret of the death of Dr. Francis Charles Martley, which took place on November 2 at Farnham, in Surrey, where he had been living in retirement. Inevitably, at meeting after meeting from 1921 onwards, after the Treasurer had presented his budget, Dr. Martley would make his way to the platform, and the meeting would listen to an incisive commentary on the financial policy of the Association. It was always in a vein of friendly criticism, it never aroused rancour, but it revealed a close study of Association accounts and balance sheets such as probably few members give to them, and it was appreciated by successive Treasurers. To Martley matters like sinking funds, investments, transactions at banks and stock exchanges, leases, reserve accounts, were a kind of second nature. Had he not preferred a medical career he might well have been a leader among chartered accountants.

The same financial acumen and business ability he brought greatly to its advantage, to the affairs of the Medical Sciences Annuity and Life Assurance Society, of the board of which for many years he was chairman. The intricacies of insurance,

are not everybody's recreation ground, but Martley exulted in them; there was nothing too recondite for him in financial or actuarial calculations, and his day of triumph was the annual meeting of that body when he was able to announce some excellent "with-profit" bonus. One felt, listening to his speeches on those occasions, packed with big figures, how much he enjoyed it all. When this war came and the staffs of insurance offices were depleted, and especially after the offices of his insurance society were destroyed, Martley took on his shoulders still more work; work for his society was the hobby of his retirement. No financial detail ever bored him.

His expertness in accounts and financial transactions generally (on behalf of other people, be it said, for he was not the man to make anything of it for himself, content as he was with his modest director's fee) was so remarkable that many people almost forgot that he was a doctor. But in fact he was a man of considerable academic distinction. He entered Cambridge in the late 'eighties, took the B.A. with honours in the Natural Sciences Tripos in 1887, and the M.A. in 1891. After training at St. Mary's Hospital he qualified as M.R.C.S., L.R.C.P., and proceeded to the M.D. Cambridge in 1895. His early work took him to Dublin, where he was demonstrator in chemistry at the Royal College of Surgeons and anaesthetist to Dr. Steevens' Hospital, a large hospital associated with the medical school. During his work in Dublin he began to take an active part in the affairs of the British Medical Association, which he had joined in 1895. He was a member of the Annual Representative Meetings in 1905 and the two following years; he also served on the Public Health Committee at headquarters at this time, and he was honorary secretary of the Section of State Medicine in 1907 at Exeter. Meanwhile he had become a Fellow of the Royal College of Physicians of Ireland and had taken the D.P.H.

After the last war, when Martley appeared again in the central work of the Association, it was as representative for Kensington, of which Division he was honorary secretary from 1920 to 1922, chairman in 1925-6, and representative for the whole period, with the exception of two years, from 1921 to 1934. In London he returned to his old hospital, St. Mary's, and worked in the Inoculation Department, where his chief was another man of close Dublin associations, Sir Almroth Wright. One of Martley's interests was blood grouping, and he wrote several papers in the *Transactions of the Medico-Legal Society*, the *Analyst*, and other journals, on the use of blood-group reactions in forensic investigation.

The B.M.A. has lost a most able and well-liked member; he was a man of great integrity and loved his profession, to which he gave without stint of the unusual abilities with which Nature had endowed him.

Dr. STUART ALEXANDER TIDEY, who died at Winchester on October 29, was born at Reading in 1858, the son of Alfred Tidey, who was an artist. From the age of 8 or 9 onwards he lived with his parents in Jersey and subsequently in various parts of the Continent, attending schools in Corsica, Switzerland, and Biberich in Germany. On returning to England he put in for a competitive student interpretership, which he just missed, and spent the next two years studying engineering at the Crystal Palace. He then entered St. Mary's Hospital, taking the London M.B., B.S. in 1888 and the M.D. and M.R.C.P. in 1891. He had taken the L.S.A. in 1886 and the M.R.C.S. in 1887, and in 1889 secured the Swiss Federal diploma in medicine at Geneva University. Dr. Tidey held the posts of house-surgeon, assistant pathologist, and curator at St. Mary's Hospital. In 1890 he started practice in Montreux, and in 1892 moved to Florence, where he was a prominent member of the British colony. From 1901 to 1912 he again practised in Montreux, and in 1912 went to British Columbia, where he combined farming with medical work. He then joined John Antle's medical mission to loggers, and was in charge of hospitals on the coast and inland. In 1914 he joined the hospital ship *St. George*, which he helped to fit out, and in 1917 was placed on the staff of the County of Middlesex War Hospital at Napsbury, near St. Albans. In 1920 he joined the Elders and Fyffes Line as surgeon on banana and passenger

boats to Central America and the West Indies, doing the voyage eight times a year until 1931, when Elders and Fyffes were shortening staff. It was characteristic of him that he was deeply disappointed at giving up the work, though at the age of 73 he might reasonably have considered that a little leisure was indicated. Every aspect of medicine and surgery interested him, and though his body was weakened by paralysis agitans his mind was active to the last. Dr. Tidey was author of articles on treatment of compression in pulmonary lesions, on the treatment of empyema and of corpulency. He was a very English man, in spite of his many foreign sojournings, quiet in speech, and retiring in manner, while setting out the gist of any subject in a few words. He was intensely interested in music and natural history, and gardened until incapacitated by gradually advancing disease.

L. P.

R. T. writes: Dr. JOHN GILFILLAN RONALD, whose death was recorded in the *Journal* of November 8, first assisted and finally succeeded his father in the practice at Larbert, which father and son between them held with distinction for over one hundred years. There is small wonder that he was constantly referred to not only locally but in Glasgow and Edinburgh as "Ronald of Larbert," a "title" based on the best foundations of all—affection and esteem. His quiet sincerity of thought and earnestness of purpose endeared him at once to all who came into contact with him. He was devoted to his profession, and concerned not at all by material gain or worldly advancement. For forty-six years he was responsible for the first-aid and ambulance instruction in a district noted for its efficiency and advancement in this work. The British Red Cross Society had in him and in Mrs. Ronald its strongest local enthusiasts. For many years he was chief of the East Stirlingshire Infectious Diseases Hospital at Camelon. Above all, Ronald was a great family doctor, a true guide, philosopher, and friend, and of the type we associate with that generation. He took upon himself the burdens of many, and no one heard him grumble or complain. To his intimate friends the burdens seemed to be weighing a little more heavily lately, but the heart was stout to the end. His illness lasted only a few hours, so that he was taken, as he would have wished, "in harness."

The following well-known medical men have died abroad: Prof. KEN KURE, who held the chair of medicine at Tokyo, aged 57; Prof. AUGUSTE DUCREY of Rome, who discovered the streptobacillus of soft chancre in 1889; Prof. LOUIS SPILLMANN, director of the dermatological clinic and for many years dean of the medical faculty at Nancy; Dr. ERNEST DE MARGNAC, one of the founders of bacteriology in Geneva, aged 96; Prof. PAUL SCHROEDER, founder of the *Deutsche Gesellschaft für Kinderpsychiatrie und Heilpädagogik*, and formerly professor of psychiatry at Leipzig University, aged 67; Dr. PILADES O. DEZZO, professor of hygiene in Buenos Aires; Dr. ENRIQUE SUNER, president of the Spanish Red Cross and formerly professor of paediatrics at Valladolid, and founder of the National Child Welfare School in 1925; Dr. GUNN HOLMGREN, professor of oto-rhino-laryngology at the Carolinska Institute of Stockholm, co-editor of *Acta Oto-Laryngologica*, aged 65; Dr. SEVERIN ANDREAS HEYERDAHL, professor of radiology at Oslo, aged 70; Dr. H. E. MENAGE of New Orleans, head of the department of dermatology of the Tulane University of the Louisiana School of Medicine; Dr. HENRY B. CHU, medical secretary of the Chinese Medical Association; Dr. HENRY KEITH SHAW, professor of paediatrics at Albany Medical College, 1906-30, and translator of Pfaunder and Schlossmann's *Diseases of Children*, aged 67; Dr. ANGEL C. SANHUEZA, professor of children's diseases in the medical faculty of Santiago de Chile for more than thirty years; Dr. SANTIAGO SRIJAY Y BAILE, founder and director of *Habana Medica*, aged 80; Dr. CLAUDE THOMAS WOLFE, professor of ophthalmology at the Louisville University School of Medicine, aged 57; Dr. MAX ISSERLIN, professor of psychiatry at Munich; and Dr. HANS BERGER, professor of psychiatry and neurology at Jena, discoverer of the electrical waves of the human brain, aged 68.

Erratum

We very much regret that through some confusion of names an announcement appeared in the *Journal* of September 6 of the death of Dr. S. W. BECKER of the University of Chicago. We have expressed our apologies to Dr. Becker and now repeat them in public at the first opportunity.

The Services

HONORARY PHYSICIAN TO THE KING

Lieut.-Colonel (temporary Colonel) S. Smith, R.A.M.C., has been appointed Honorary Physician to the King in succession to Major-General R. C. Priest, C.B., late R.A.M.C., who has retired.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL NAVY

Surgeon Lieut. DERMOT HARRY TUTHILL DUGGAN, R.N.V.R. (H.M.S. *Ardent*), who was announced as "Missing" in the *Journal* of August 10, 1940 (p. 207), is now reported "Missing, Believed Killed in Action at Sea." He was the only surviving son of the late Captain G. G. Duggan, who was killed at Gallipoli in 1915, and Mrs. G. de Courcy Wheeler of Foxrock, Co. Dublin, and was educated at Trinity College, Dublin, graduating M.B., B.Ch., B.A.O. in 1935, proceeding M.D. four years later. He had been a member of the British Medical Association since 1936. On the outbreak of war he entered the R.N.V.R. as surgeon lieutenant.

ROYAL ARMY MEDICAL CORPS

Prisoner of War

War Substantive Captain Ian Rainy Ingram MacDonald.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Francis Peyton Rous, M.D., F.R.S., of the Rockefeller Institute for Medical Research, has been elected an honorary Fellow of Trinity Hall. Dr. Peyton Rous holds the honorary degree of Sc.D. of Cambridge and was Linacre lecturer at the University in 1929.

Names of candidates for the M.Chir. examination should be sent to the Registry by December 30; the examination begins on February 17.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The annual meeting of Fellows and Members will be held at the College in Lincoln's Inn Fields on Thursday, November 20, at 2.30 p.m., when a report from the Council will be laid before the meeting.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting of the Royal College of Physicians of Edinburgh, held on November 4, with the President, Dr. Charles McNeil, in the chair, Dr. B. Reid (Hellingley), Dr. J. L. Cowan (Penicuik), Dr. A. J. Rhodes (Edinburgh), Dr. A. D. Stewart (Edinburgh), Dr. A. Joe (Edinburgh), and Dr. J. B. Borthwick (Edinburgh) were elected Fellows of the College.

Hill Pattison-Struthers Bursaries in Clinical Medicine were awarded to Saul Jerome Blau and Louis Kaywin, and Wood Bursaries to Norman T. Speirs and John Alexander Loraine.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the annual meeting of the Royal Faculty of Physicians and Surgeons of Glasgow the following officers were elected for the ensuing year: *President*, Mr. Roy F. Young; *Visitor*, Mr. James H. MacDonald; *Honorary Treasurer*, Mr. William Richard; *Honorary Librarian*, Dr. W. R. Snodgrass; *Representative on General Medical Council*, Mr. J. Scouler Buchanan.

According to *South Africa* of October 18, only 35 Europeans died of disease in East Africa in the first eight months after the outbreak of the war, and the incidence of ill-health during the East African campaign was not much higher than in corresponding age groups of the industrial population in tropical climates. No cases occurred of plague, louse-borne typhus, and sleeping sickness among the men serving under General Cunningham. Owing to the universal inoculation of the Forces only one case of typhoid fever was reported.

Medical News

Sir Farquhar Buzzard will deliver a lecture on "Hospital Regionalization" at the Weston Hotel, Bath, on Thursday, November 20, at 5.30 p.m. All Service medical officers and civilian practitioners will be welcome.

A Chadwick Public Lecture entitled "Advances in Dermatology during the Past Forty Years" will be given by Dr. S. Ernest Dore, at the Westminster Hospital Medical School, 17, Horseferry Road, Westminster, S.W.1, on Thursday, November 27, at 2.30 p.m.

A squadron leader of the Royal Air Force Medical Service has written to B.M.A. House about the kindly reception given to him and to other members of the medical profession serving in the Forces by the South African Medical Association in Capetown on their brief visit to that city. Every facility for recreation, amusement, and matters of professional interest was given by the secretary, Mr. C. L. Darley-Hartley; and the kindness and hospitality of the citizens of Capetown were deeply appreciated by the visitors. The writer also refers to the "splendid bureau" near the dock gates, which is organized and run by the ladies, who put medical officers of the Services in touch with members of the profession in Capetown. Other members have mentioned the warm welcome received on their arrival at South African ports, and there was a note offering hospitality in a recent number of the *South African Medical Journal*.

Under the auspices of the Board of Education a conference on Food Education was held on November 7 and 8 at Gas Industry House, Grosvenor Place, S.W. The chair was taken at the opening meeting by the President of the Board of Education, the Rt. Hon. R. A. Butler, M.P. There were four lectures on the first day: Dr. Edouard-Jean Bigwood discussed the problem of improving health by influencing diet; Dr. Margaret Wright, rationed foods as the basis of a sound diet; Dr. Barnett Stross, food and health; and Dr. May Smith, some problems in teaching a practical subject. The morning of November 8 was devoted to a series of discussions on practical problems of food education, introduced by various speakers.

With the October number Dr. J. Y. Dent has succeeded Dr. T. N. Kelynack as editor of the *British Journal of Inebriety*.

The August issue of the *American Journal of Diseases of Children* contains a sympathetic obituary notice of Sir Frederic Still.

A severe outbreak of rabies has recently occurred in the East of Germany, according to the *Schweizerische Medizinische Wochenschrift*.

Emeritus Professor Ralph Stockman, M.D., has been elected a vice-president and Prof. E. W. H. Cruickshank, M.D., and Sir J. Donald Pollock, M.D., members of the council of the Royal Society of Edinburgh.

Mr. Robert John McConnell, M.Ch., honorary surgeon to the Ulster Hospital, Belfast, has been commended for brave conduct in civil defence.

The Pavlov laboratories in Leningrad are conducting research on the effect of various pharmaceutical substitutes on the higher nervous system. The work is going on regularly and systematically despite the proximity to the front.

The Canadian Red Cross Society is equipping a 25-bed emergency hospital for the Polish Army recruiting station at Windsor, Ontario. A 45-bed hospital will also be built for the Polish training centre at Owen Sound.

A typhus epidemic is reported to be raging in the ghetto of the Polish town of Miedrzyec.

The manufacture of all drugs not vitally necessary, and of all cosmetics without exception, has been forbidden in Germany owing to the shortage of raw materials.

Owing to the lack of offers of "Aryan" blood for transfusion the Rumanian Red Cross has announced that Jewish blood will be accepted.

No. 43

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended October 25.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week of last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 176 great towns in England and Wales (including London), (b) London (administrative county), (c) the 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

Between the week under review and the preceding week there were only small differences in the number of cases of infectious diseases notified in England and Wales. The largest numerical deviations were those for scarlet fever, an increase of 29 cases, and for measles, a decrease of 38 cases. The increase in scarlet fever was confined to the Midland and Northern counties, where 95 cases in excess of last week's were recorded, while in the southern sections of the country there was a decrease, notifications being 65 fewer. In Scotland there was a general tendency for notifications to rise, with the exception of diphtheria, of which 32 cases fewer than in the previous week were notified.

Dysentery

The notifications for dysentery in England and Wales fell from 143 to 139. Increases were reported in several counties, the largest of the new local outbreaks being in Essex (Epping U.D., 12). In Scotland the number and distribution of cases have undergone little change in the past three weeks. The largest totals are those of Lanark County (28), Edinburgh (19), and Dundee (14).

Poliomyelitis

No change occurred in the number of cases of poliomyelitis in England and Wales compared with the previous week's total, when the largest number of notifications since last September was recorded. The cases were widely distributed, and only six administrative areas reported more than 1 case. These areas were Dorsetshire (Bridport R.D., 3), Lancashire (Manchester C.B., 3), Cambridgeshire (Cambridge M.B., 2), Middlesex (Edmonton M.B., 2), Norfolk (Mitford and Launditch R.D., 2), Oxfordshire (Bullington R.D., 2). Counties which had a single case in more than one administrative area were Essex (3), Hertfordshire (4), London (5), and Surrey (5). In Scotland 8 cases, compared with 2 in the preceding week, were notified (Edinburgh 4, Glasgow 2, Dundee 1, Fife County 1). Two deaths have been reported from a small outbreak in Enniskillen, Northern Ireland.

Diphtheria in Scotland

Owing to the increasing proportion of the *gravis* type of bacillus occurring among cases of diphtheria, the medical authorities of Scotland have launched an intensive campaign for the increased immunization of children. As a result of publicity earlier in the year 56% of the parents had responded—that is, 600,000 of the child population of 1,120,000 have already been treated. The present effort is an attempt to immunize at least 85% of the children.

Reports of medical officers in England have suggested that the *gravis* type is occurring in a larger proportion of cases throughout the country. No comparisons can be made, since it is only in a few hospitals that *C. diphtheriae* is typed as a routine procedure, and it is unsafe to generalize from results obtained from relatively small areas.

Week Ending November 1

The returns of infectious diseases for the week included the following: scarlet fever, 1,204; whooping-cough, 1,955; diphtheria, 915; measles, 624; cerebrospinal fever, 102; poliomyelitis, 23; dysentery, 123; paratyphoid, 35; typhoid, 20.

A. A. Holbrook (*Arch. intern. Med.*, 1941, 68, 294) studied the blood picture in 56 chicken-pox patients and 15 controls, with the following result: A drop in the total white blood cell count to 5,000 per c.mm. or less, principally at the expense of the neutrophil polymorphonuclear cells, combined with the appearance of immature lymphocytes and plasma cells, is the significant feature in the blood picture of varicella. When this combination is found in the incubation period, the onset of the rash may be foretold with fair accuracy. When such findings are wrong, the cases may be examples of the non-eruptive form. Holbrook suggests that a strong lymphocytic reaction in varicella may be decisive in producing lymphatic leukaemia in susceptible persons.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aetiology Westcent, London*; SECRETARY, *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Persistent Skin Condition after X Rays for Pruritus Ani

S. P. writes: I am wondering if a note in your "Queries" column would bring out any helpful suggestions in the following case. The patient, a woman aged 55, married, with one child aged 26, some eight years ago had pruritus ani (not seen by me), and was given x-ray therapy. There is little doubt that the dosage was excessive. Since then the skin of the perineum has been breaking down constantly, seldom remaining even reasonably healthy for more than two or three months at a time. The patient herself is of a highly strung and somewhat neurotic disposition, and has in the past suffered from attacks of dermatitis herpetiformis. She has been seen by half a dozen dermatologists, and psychotherapy has been tried. The remedies suggested have been almost legion: tannic acid, dyes, Unna's paste, thorium-x, most of the vaunted antipruritic powders and ointments, silver nitrate cautery, and so forth. About the only thing I can think of now is skin grafting, but I should imagine that the risk of failure would be considerable in view of the locality.

Stabbing Heel Pains in Rheumatoid Arthritis

W. R. S. writes: A woman with advanced rheumatoid arthritis suffers from stabbing pains in the heel, coming on mostly during the night and disturbing her rest. They are relieved if she puts her foot out of bed. Advice as to prevention or treatment would be much appreciated.

Treatment of Chilblains

Dr. P. BINNINGTON (Hull) writes: May I suggest that Dr. Frank Matthews and "Stasis" (October 18, p. 568) try Lugol's solution for the treatment of chilblains. I too have found the use of calcium preparations disappointing, and for some years I have prescribed Lugol's solution, 12 minims, to be taken in half a tumbler of water three times daily directly after meals, with good effect. It will clear up even severe ulcerated cases, and if started at the onset of the condition a few days' treatment suffices. Unfortunately Lugol's solution is not pleasant to take, but my experience is that it does give relief.

Income Tax

Allowances, 1941-2

"R.A.F.V.R." sends particulars of his assessment for 1941-2, and asks whether further allowances can be claimed.

** The personal allowance given (£140) is the amount applicable to a married man. The life assurance relief (£15 at 3s. 6d. in the £) may cover payments under the contract with the Medical Sickness Society; if not a supplementary claim should be made in respect of those payments. It is improbable that any allowance can be obtained for use of car, as it will probably be held that the car is not "necessarily" used "in the performance of the duties," and that any such necessity would presumably be met by R.A.F. transport.

Purchase of Goodwill by Instalments

R. C. inquires in what circumstances payments of instalments "can be put against income tax."

** Normally the purchase price of goodwill is either a definite amount or an amount unknown at the date of purchase to be deter-

mined by subsequent events. In such cases the amount to be paid is clearly "capital"—it is not taxable in the hands of the vendor whether he receives it in a lump sum or in instalments, and the purchaser cannot obtain any relief in respect of it. If, however, the purchase agreement is so worded as to amount to the sale of the goodwill in consideration for a fixed or fluctuating annuity, then the payer is entitled to deduct tax at standard rates from the gross amounts which he pays, and the vendor of course suffers tax accordingly. Such cases are presumably rare, as the effect is to place the income-tax burden on the recipient of what is in common sense, whether in law or not, a capital sum.

LETTERS, NOTES, ETC.

International Hospital Association: United Kingdom Council

It is thought by many that the war has rendered defunct all international associations. One at least—the International Hospital Association—is not dead, although it may be moribund. Signs of its revival are actually appearing, for a conference has been called to discuss the position of hospitals the world over after victory and the coming of peace. The United Kingdom Council of the I.H.A., of which Mr. W. McAdam Eccles, M.S., F.R.C.S., is chairman, is sponsoring this line of treatment for the patient. The meeting will be held in the Great Hall of the British Medical Association House, Tavistock Square, London, on Tuesday, November 25, from 2 to 5 p.m. A paper will be read by Prof. A. T. Jurasz, dean of the Polish Medical Faculty of the University of Edinburgh, on "The International Position of Hospitals after Victory and the Coming of Peace," and a second will be on "The Position of Hospitals in the English-speaking Countries after the Coming of Peace." Representatives, both Governmental and medical, from fifty-four countries have been asked to attend, and the Minister of Health, Mr. Ernest Brown, has signified his intention to honour the gathering by coming. Admission will be by ticket only. Any further information may be obtained from Mr. F. W. Adams; honorary secretary, 17, Bloomsbury Square, London, W.C.1.

"First Aid to the Injured"

Dr. E. A. WELSH (Felton, Morpeth) writes: I would like to congratulate Dr. J. C. Hodgson on his letter regarding the teaching of first aid (October 25, p. 595). After two years of war we are still receiving from the St. John authorities the same examination papers that have been used for the past twenty years, and fully half the questions have no bearing whatever on wartime injuries. If the authorities are too slow to realize our needs it is to be hoped that lecturers will concentrate on the essentials which he mentions, and not waste time on so much irrelevant matter.

Abbreviated Treatment for Bilharziasis

Dr. F. GORDON CAWSTON (Durban, S.A.) writes: By injecting into the deltoid muscle from 3 to 3½ c.cm. of anthiomaline three or even four times in a week I seem to have effected a cure of *Schistosoma haematobium* infection in three weeks among out-patients continuing their work though reporting some generalized muscular pain. This would indicate that the eggs are disintegrated and the adult worms destroyed most readily by giving the drug sufficiently often to prevent their recovering from one dose before the next, and before much of the drug already administered has been eliminated. With *mansoni* infection escape of the eggs is too uncertain to be much of a guide as to when treatment may safely be discontinued, and 25 to 30 grains of tartar emetic is needed until such time as careful investigation has revealed the clinical equivalent of anthiomaline.

The Grenfell Association

Owing to the war the Grenfell Association is not offering new Christmas cards for sale this year. The purpose for which this sale was arranged—to get funds towards the association's welfare work among the people of Newfoundland and Labrador—is as urgent as ever, and the association is therefore selling instead new photograph postcards of Labrador (2d. each, postage extra) and attractive coloured postcards (packet of six 1s.). They may be obtained from the offices of the Grenfell Association, 66, Victoria Street, S.W.1.

Disclaimer

Mr. G. RIGBY-JONES, surgical registrar, National Temperance Hospital, writes: Incorrect reports and somewhat unfortunate publicity attached to a severe case of burns which I have treated by the Bunyan-Stannard method have resulted in a widespread belief that saline was used. This is not the case. The solution was electrolytically prepared hypochlorite.

COMBINED ACTIVE AND PASSIVE IMMUNIZATION AGAINST DIPHTHERIA

I. STUDIES OF ANTITOXIN RESPONSE IN NORMAL STUDENTS

BY

A. W. DOWNIE, M.D., D.Sc.

A. T. GLENNY, B.Sc.

(From the Emergency Public Health Laboratory, Cambridge; the Wellcome Physiological Research Laboratories, Beckenham; the Department of Bacteriology, Sheffield University; and the Emergency Public Health Laboratory, Oxford)

Though in veterinary medicine the prophylactic treatment by combined active and passive immunization of animals has been in vogue since the beginning of the century, it is only within recent years that the method has been applied to the prevention of human disease. The reason for this is not far to seek. In the treatment of animals risks can be taken that are seldom justifiable with man. In such diseases as anthrax, swine fever, swine erysipelas, rinderpest, and African horse-sickness the vaccinating agent used is the living organism. When given along with a suitable dose of protective serum it leads to the more or less permanent protection of the animal after the initial temporary protection by the injected serum has worn off. The essence of the method consists in stimulating an active, under cover of a passive, immunity. In human medicine there are few infective diseases in which a powerful antiserum is available, and in the two outstanding examples, diphtheria and tetanus, no one has dared to attempt active immunization by injection of the living organisms. It was not, therefore, till a safe non-living and non-toxic vaccinating agent was made available by the discovery of formol toxoid (Glenny and Südmersen, 1921; Glenny and Hopkins, 1923; Ramon, 1923, 1928) that the possibility of combining active and passive immunization in the prophylactic or therapeutic treatment of these two diseases became practicable.

Review of Previous Work

Ramon and Laffaille (1925) studied the production of tetanus antitoxin in guinea-pigs. The animals were divided into four lots. Lot A received 1 c.cm. of anatoxin (formol toxoid) alone. Lot B received 1 c.cm. of anatoxin mixed with antitetanic serum containing 4,500 antitoxin units (A.U.). Lot C received 1 c.cm. of anatoxin and 4,500 A.U. of serum given simultaneously into different sites. Lot D received 4,500 A.U. of serum alone. Sixteen days later some of the animals in each lot were tested for their resistance to the injection of tetanus toxin. Lot A was found to withstand about 60 m.l.d., whereas none of the other lots withstood even 2 m.l.d. The conclusion was therefore drawn that the serum had interfered with the immunizing action of the anatoxin.

To see, however, whether it had also affected the sensitizing action of the anatoxin, the remaining animals in each lot were given 1 c.cm. of anatoxin 20 days after the first injection. Seven days later they were tested for their resistance to tetanus toxin. The animals of Lot A withstood several hundred m.l.d. The animals of Lot C withstood 10 to 50 m.l.d. The animals of Lots B and D proved almost as susceptible as non-immunized controls. This experiment showed that the simultaneous administration of serum to the animals of Lot C, though it had prevented their immediate antitoxin response, had not entirely destroyed the sensitizing effect of the anatoxin and the consequent ability of the animals to respond more rapidly to a second

dose. It also showed that the over-neutralized mixture given to the animals of Lot B was valueless in this respect. Not only did it fail to give rise to antitoxin production, but it likewise failed to sensitize the tissues and enable them to respond to a fresh injection of anatoxin. These experiments were repeated on rabbits with substantially the same results.

In 1928 Ramon described the general properties of anatoxin. Discussing combined active and passive immunization, he considered that the method should not be used except in cases of necessity, since it is less successful in producing active immunity than vaccination with anatoxin alone.

This conclusion was supported by observations on a small number of children described by Martin, Loiseau, and Laffaille (1928). In a school where diphtheria had broken out these workers inoculated 9 children with 0.5 c.cm. of anatoxin and 14 children with the same dose of anatoxin followed half an hour later by 1,000 units of diphtheria antitoxin. All received a second dose of 1 c.cm. of anatoxin 30 days later, and a third dose of 1 c.cm. after another fortnight. Three weeks after the last injection the children were Schick-tested. All the 9 children who were given anatoxin alone reacted negatively, whereas 2 of the 14 children who were given serum as well as anatoxin were Schick-positive.

In 1938 Ramon and his colleagues returned to the subject. Working this time with rabbits, they found that animals given 4 c.cm. of tetanus anatoxin and bled a fortnight later had an antitoxin titre of about 1/5 A.U. per c.cm., whereas those injected simultaneously but into different sites with 4 c.cm. of anatoxin and with serum containing 300 A.U. had a titre of less than 1/600 A.U. After a second dose of anatoxin, however, the titre of the first group was between 2 and 7.5 A.U., and of the second group between 7 and 8 A.U.

In another experiment animals receiving anatoxin alone had a titre 18 days later of 1 A.U. per c.cm., whereas those given both anatoxin and serum had a titre of less than 1/300 A.U.; but 14 days after a second injection of anatoxin the animals of both groups had a titre of about 7 A.U. It appears from these experiments, therefore, that serum delays or interferes with the primary response to anatoxin, but does not destroy the sensitizing power of the anatoxin and the consequent ability of the animal to respond rapidly to a second dose. This conclusion, however, was not drawn by Ramon and his colleagues.

In a later paper Ramon, Richou, and Maccolini (1939) made similar experiments on rabbits using diphtheria anatoxin and serum. Each lot contained 6 animals. Lot A received 3 inoculations, at five-day intervals, of 0.5, 1, and 2 c.cm. respectively of anatoxin. Lot B received in different sites on the same day 0.5 c.cm. of anatoxin and serum containing 3,250 A.U., followed at five-day intervals by injections of 1 and 2 c.cm. of anatoxin only. Lot C received both anatoxin and serum at each of the three injections, the anatoxin doses being the same as before, and the serum doses being each 325 A.U. The animals were bled 1, 4, 6, 8, and 12 weeks after injection, and then at intervals up to 15 months. The sera of the animals, in each lot were pooled and titrated for antitoxin. In all three groups the maximum titre of 3 to 4 units was recorded after a week; it then fell gradually till after 15 months it was 1/20 to 1/10 A.U. per c.cm. It was therefore concluded that the

simultaneous inoculation of serum does not interfere at all with the development of active immunity following the administration of anatoxin.

This conclusion, which is very much less cautious than that reached in 1925, is seriously open to question. The number of animals used in Ramon's last experiment was small, and the administration of a very large dose of serum to the animals of Lot B and of three successive doses of serum to the animals of Lot C makes it difficult to interpret the antitoxin titres during the first few weeks following the injections. It is conceivable that the serum may have interfered with the active immunity response in the early stages, but that this interference was masked by the presence of circulating antitoxin remaining from the serum injections.

Other papers have been published by Ramon (1938, 1940), based partly on observations made on actual cases of diphtheria treated by the combined method, which have led him to conclude that serum therapy does not interfere at all with the development of active immunity. Since in patients suffering from diphtheria the issue is apt to be confused by the presence of toxin formed by the infecting bacilli themselves, it is hardly worth-while abstracting these papers or those of his colleagues on the same lines.

Reviewing Ramon's work as a whole, it will be seen that his earlier experiments were better designed than his later ones to decide whether the administration of serum along with anatoxin interferes with the antibody response of the tissues. It is therefore understandable, though regrettable, that Ramon passed between 1925 and 1940 from an attitude of caution to one of dogmatic assertion.

The experience of other workers on combined active and passive immunization is conflicting. Glenny, Buttle, and Stevens (1931) found that if toxoid was inoculated subcutaneously into guinea-pigs most of the animals had a serum antitoxin content of between 1/100 and 1 A.U. per c.cm. 4 to 6 weeks later. But if antitoxin was given intravenously in an amount sufficient to neutralize all the toxoid injected, either at the time of inoculation of the toxoid or up to 3 days later, no antitoxin was formed. The longer the interval between the inoculation of toxoid and the inoculation of serum, the less was the degree of inhibition of antitoxin production. Even with a 21-day interval, however, antitoxin production was still not as good as in the controls that were given no antitoxin. It thus appears that neutralization of toxoid by antitoxin diminishes the antitoxin response, and that if combined active and passive immunization is to be successful an excess of toxoid must be present in the tissues.

Frey and Schmid (1939) injected 20 children with 1 c.cm. of alum-precipitated toxoid (A.P.T.) subcutaneously and 1,000 to 2,000 units of diphtheria antitoxin intramuscularly. The children were bled at intervals and the antitoxin content of their serum was titrated. All of them showed a fall in the initial value after injection, and none showed any development of fresh antitoxin. Most of the observations, however, were made within 4 weeks of the injection, and no second dose of A.P.T. was given. Since it is well known from the observations of Glenny and Südmersen (1921) and Glenny (1925, 1931) that the main rise in antitoxin does not occur till after the secondary stimulus has been given, the results obtained by Frey and Schmid are not surprising. Indeed, they would hardly be worth noticing were it not for the fact that they were made the basis of an editorial in the *Journal of the American Medical Association* (1939, 113, 1884), in which the following conclusion drawn from the work of Frey and Schmid and of Paschla (see later) was emphasized: "Combined active-passive immunization is not feasible in human medicine, the two types of immunization being incompatible with each other."

Much the same criticism applies to the observations, in Mexico, of Leon, Escarza, and Navarro (1939), who gave a single dose of 1 to 1.5 c.cm. of A.P.T. and 1,000 to 1,500 units of diphtheria antitoxin to 80 Schick-positive reactors. One month later, of 42 who were retested 6 were still Schick-positive. Two months later, of 38 who were retested 9 were Schick-positive. As in Frey and Schmid's work, only one dose of A.P.T. was given, and no comparison was made with a group of persons immunized by the active method alone.

Gundel and König (1938) made some very interesting observations on guinea-pigs. They injected them with various emulsified and alum-precipitated toxoids or with toxoid-antitoxin flocules (T.A.F.), together with a dose of anti-diphtheria serum, and tested their immunity at intervals to infection with living diphtheria bacilli of the gravis and mitis types. In brief they found that (a) animals given serum alone—500 A.U.—were protected for less than a fortnight; (b) formal toxoids or T.A.F. alone produced partial or complete immunity within

a fortnight; (c) A.P.T. produced within a fortnight an immunity that was more complete and lasted longer than that obtained by injection of formal toxoids or T.A.F.; (d) the combination of formal toxoid and serum protected guinea-pigs for a week, but left them susceptible again within a fortnight; (e) the combination of A.P.T. and serum protected them for a week, left them susceptible during the 2-4-week stage, and then protected them again later. In other words, the passive immunity conferred by the serum wore off in a week or two and left the animals susceptible until active immunity resulting from the A.P.T. began to develop 4 to 6 weeks after injection. It is clear from Gundel and König's work that serum does interfere with the response of the body to an active immunizing agent. Unfortunately these workers did not give a second injection of toxoid. They concluded, however, that if combined active and passive immunization is to be satisfactory a dose of A.P.T. must be given which is sufficiently large to leave enough unneutralized toxoid at the injection site to stimulate the development of antibody after the serum has disappeared from the circulation.

Whether this conclusion is correct or not it is difficult to say, but, provided two injections of toxoid are given, neither of the doses need be very large. Gierthmühlen and Voges (1939), for example, in a nursery home where diphtheria had broken out, inoculated children with 0.3 c.cm. of A.P.T. along with 1,000 units of antitoxin. Three weeks later they gave a second dose of A.P.T. of the same amount. All children were Schick-tested six months later, and all were Schick-negative. It is interesting to note that 3 out of 19 children who had received only their first dose of A.P.T. developed diphtheria, and that of 43 who had received both first and second doses of A.P.T. two developed diphtheria within 21 to 46 days after the first inoculation. The disease, however, was of an extremely mild type. These observations support those made by Gundel and König in showing that there is probably a period of relative susceptibility between the time when the passive immunity due to the serum has worn off and the time when the active immunity due to the A.P.T. has developed. They do show, however, in addition, that, provided a second dose of A.P.T. is given, satisfactory immunity is produced at any rate within six months.

The observations of Paschla (1939) do not bear out Gundel and König's results. Paschla found that of 39 children with an initial titre of less than 0.005 A.U. per c.cm. who were given a single dose of 0.2, 0.5, or 1 c.cm. of A.P.T., 20 formed no antitoxin within 6 weeks, 11 reached a titre of about 0.03 A.U., and 8 reached a titre of between 0.5 and 20 A.U. When, in another series of 22 children, he gave one dose of 0.2, 0.5, or 1 c.cm. of A.P.T. along with 1,000 units of antitoxin, 21 completely failed to respond. Paschla therefore concludes that in children with no initial antitoxin in their blood the administration of serum hinders the response to A.P.T. In children who had already been exposed to diphtheria and whose blood contained some antitoxin, the administration of serum had no inhibiting effect. On the other hand, from the point of view of treatment, it had no advantage, since these children responded very rapidly to an injection of A.P.T. alone.

Fjord-Nielsen (1940) made some interesting observations, complementary to those of Glenny, Buttle, and Stevens (1931), on the effect of serum in delaying antitoxin formation. Working with guinea-pigs, she found that when A.P.T. and serum were given simultaneously no antitoxin was formed within 4 weeks, though the animals became sensitized and responded more readily to a second dose of A.P.T. If the first dose of A.P.T. was given 3 days after the serum, and a second dose of A.P.T. 4 weeks later, the antitoxin titre of the guinea-pigs' serum was higher than when the A.P.T. and serum were injected simultaneously. If the interval between the serum and the first dose of A.P.T. was lengthened to 7 days, then the final titre was higher still. If it was lengthened to 14 days a result was obtained that was as good as if no serum at all had been given. From these experiments it would appear that the administration of serum interferes with antitoxin production but does not destroy, though it may weaken, the sensitizing effect of the first dose of A.P.T.

It is not surprising that the results of different workers whose experiments varied in so many important particulars should have been conflicting and at times apparently contradictory. Looking at them, however, as a whole it is difficult to avoid the conclusion that the simultaneous administration of serum with toxoid interferes with the primary response of the tissues, but does not destroy, though it may weaken, the sensitizing power of the toxoid.

which enables the tissues to respond to a second dose of toxoid by the rapid production of antitoxin. This is essentially the same conclusion as was reached, but subsequently abandoned, by Ramon and his colleagues.

Description of Experimental Observations

In view of the findings of previous workers it seemed important to choose (1) a dose of toxoid that was small enough to reveal any possible inhibitory action of the serum; (2) a dose of serum that was not so large as to conceal the active formation of antitoxin in the body as the result of the injection of toxoid; and (3) a toxoid in the form of the alum precipitate to ensure as little interference as possible by the action of the serum. The general plan of the experiments was therefore as follows.

Observations were made at Oxford, Cambridge, and Sheffield on third-year medical students, the majority of whom were between 20 and 22 years of age. In addition a small number of observations were made at Turner's Court Training Colony, near Oxford, on boys all but two of whom were between 14 and 19 years of age.

The subjects were first of all Schick-tested. About 6 to 8 c.cm. of blood was withdrawn from those giving a positive reaction, and sent to Mr. Glenny at the Wellcome Physiological Research Laboratories to be titrated for diphtheria antitoxin. The Schick-positive reactors were then divided into two groups, A and A+P. The subjects in Group A (active immunization) received 0.1 c.cm. (5 Lf) of Burroughs Wellcome's alum-precipitated toxoid (A.P.T.) into the left upper arm. Those in Group A+P (active plus passive immunization) received 0.1 c.cm. of A.P.T. into the left upper arm and 350 to 500 units of Burroughs Wellcome's refined diphtheria antitoxin (Pope, 1938, 1939) into the right upper arm. All injections were made into the deep subcutaneous tissue. Four weeks later the subjects were again bled, and were then given 0.3 c.cm. of A.P.T. into the right upper arm. Eight weeks after the second dose of A.P.T. the subjects were bled for the third time and were again Schick-tested. The results of the Schick test were read usually 3 to 5 days later, and any person who still reacted positively was given another dose of 0.3 c.cm. of A.P.T.

Though this was the general plan of the observations, departures were made from it at Cambridge and at Sheffield for various reasons. At Cambridge in one series of students the third bleeding was made 6 weeks instead of 8 weeks after the second dose of A.P.T. In another set of students only active immunization was given. In still further sets of students additional bleedings were made 12 to 23 weeks after the second dose of A.P.T. In these instances the final Schick test was not performed till after the last bleeding had been done. At Sheffield the intervals between the two immunizing doses, and between the second dose and the third bleeding, were rendered very irregular owing to enemy action.

The relevant facts relating to the different sets of observations are set out in Table I.

TABLE I.—Number and Type of Observations Made

Set	Place	Time	Original No. in Group		No. of Units of Antitoxin	Time Interval in Weeks between			
			A	A-P		1st and 2nd Bleeding	2nd and 3rd Bleeding	2nd and 4th Bleeding	2nd Bleeding and Schick Test
TC	Turner's Court	Michaelmas, 1939	8	9	350	5	8	—	8

S	Sheffield	"	26	25	500	4-10	8-10	—	8-10
Total			148	131					

A=Active immunization. A-P=Combined active and passive immunization.

The total number of subjects recorded in the table is 279. In fact rather more took part in the trials, but in analysing our figures we have excluded all initially Schick-positive reactors whose serum contained 1/1,000 unit per c.cm. or more of antitoxin. The figures recorded in this paper refer exclusively to subjects whose serum at the time of the first immunizing injection contained less than 1/1,000 unit per c.cm. Unfortunately a history of immunization was obtained only from the O2 and C2 sets of students. Of these, 7 in the A group and 3 in the A+P group had been immunized or Schick-tested pre-

viously. Since none of them contained as much as 1/1,000 unit per c.cm. of antitoxin in their blood they have been included in our figures.

Results

COMPARISON BETWEEN THE ANTITOXIN PRODUCTION OF GROUPS A AND A+P

In recording the results it will be convenient first of all to deal with those series of observations in which the original plan of the experiments was strictly followed.

In Table II are included the observations on Sets O1, O2, C1, and C2 of Oxford and Cambridge students who were bled 4 weeks after the first immunizing dose of A.P.T. or of A.P.T. plus serum. In this and in subsequent tables it has been thought wise, owing to the relatively small number of sera examined and the wide variations in the amounts of antitoxin contained in them, to report the results in simple frequency tables rather than to work out arithmetic mean titres. Here and throughout the paper all antitoxin figures are expressed per c.cm. of serum.

TABLE II.—Oxford and Cambridge Students: Sets O1, O2, C1 and C2. Antitoxin Titres 4 Weeks after First Immunizing Dose

Antitoxin Units per c.cm. of Serum	A		A-P	
	No.	%	No.	%
Good response: 1/50 or more	14	(12%)	3	(3%)
Fair response: 1/100 to 1/500	7	(6%)	57	(61%)
Poor or no response: 1/1,000 or less	95	(82%)	34	(36%)
Total	116	(100%)	94	(100%)

A=Active immunization with 0.1 c.cm. of A.P.T.

A-P=Ditto, plus 400 to 500 units of antitoxin.

$\chi^2 = 73.527$, $P < 0.000001$.

Note.—The term "response" is hardly justifiable in the A+P group, but its use is convenient.

It will be observed that the proportion of sera containing 1/500 unit or more of antitoxin was far higher in the A+P than in the A group—64% as opposed to 18%. In the small class of sera containing 1/50 unit or more, however, the relation was reversed. The difference in antitoxin distribution between the two groups is seen by the χ^2 test to be far greater than is likely to have arisen by chance alone.

These facts are best explained on the assumption: (a) that the antitoxin in the A-P group of sera was mainly residual antitoxin—i.e., the remains of the antitoxin that was injected four weeks previously; and (b) that a single dose of 0.1 c.cm. of A.P.T. gives rise to little or no antitoxin response within four weeks except in a very few persons who have had previous experience of the diphtheria bacillus; in these it acts like a secondary stimulus (Glenny, 1925, 1931; Glenny and Südmersen, 1921), and gives rise rapidly to a considerable amount of antitoxin. Evidence in support of assumption (a) will be afforded at a later stage of this paper. In support of assumption (b) are the observations

of Paschla (see above) and of Fraser (1940), who found that of 50 children who had been immunized 5 years previously and whose serum antitoxin content had fallen to below 1/50 unit per c.cm. all responded rapidly to the reinjection of a single dose of 0.1 c.cm. of toxoid, 80% within 5 weeks having more than 1/2 unit per c.cm. It is also supported by examination of the records of students in the O2 and C2 groups who gave a history of previous immunization or of Schick-testing. Of 7 such students in the A group all but one had 1/10 unit or over 4 weeks after injection, and of 3 such students in the

A+P group 2 had 1/10 unit or over. Unfortunately a record of the immunization histories of the O1 and C1 sets of students was not available.

The antitoxin titres in Sets O1, O2, and C2 of Oxford and Cambridge students 8 weeks after the second immunizing dose of A.P.T. are recorded in Table III.

TABLE III.—Oxford and Cambridge Students: Sets O1, O2, and C2. Antitoxin Titres 8 Weeks after Second Immunizing Dose

Antitoxin Units per c.cm. of Serum	A	A+P	Total
	No.	No.	
Good response: 1/50 or more ..	57 (65%)	22 (33%)	79
Fair response: 1/100 to 1/500 ..	20 (23%)	25 (38%)	45
Poor or no response: 1/1,000 or less ..	11 (12%)	19 (29%)	30
Total	88 (100%)	66 (100%)	154

A = Active immunization with 0.1 c.cm. and 0.3 c.cm. of A.P.T. at 4 weeks' interval.

A+P = Ditto, plus 400 to 500 units of antitoxin at time of first injection.

$\chi^2 = 15.366$. $P = 0.00047$.

The results are seen to be very different from those in Table II. Of those in Group A 65% had responded well by producing 1/50 unit or more of antitoxin, as against only 33% in Group A+P. The χ^2 test shows that such a difference in distribution can hardly have been due to chance.

It may therefore be concluded that, although 4 weeks after the first immunizing dose the average antitoxin titre is considerably higher in the A+P than in the A group, 8 weeks after the second injection the situation is reversed. From this the inference can be drawn that the administration of serum along with the first dose of A.P.T. leads to a lower antitoxin response, as determined by observations made 8 weeks after the second injection of A.P.T., than that due to A.P.T. alone.

We may now examine the results on all the subjects, including those that were not treated in strict accordance with the original plan. Table IV records the antitoxin titres on Sets TC, O1, O2, C1, C2, and S of students at Turner's Court, Oxford, Cambridge, and Sheffield, at an average of about 4½ weeks after the first immunizing dose.

TABLE IV.—Turner's Court, Oxford, Cambridge, and Sheffield Students: Sets TC, O1, O2, C1, C2, and S. Antitoxin Titres 4 to 10 Weeks (average 4.4 Weeks) after First Immunizing Dose

Antitoxin Units per c.cm. of Serum	A	A+P	Total
	No.	No.	
Good response: 1/50 or more ..	20 (14%)	7 (6%)	27
Fair response: 1/100 to 1/500 ..	11 (7%)	67 (52%)	78
Poor or no response: 1/1,000 or less ..	116 (79%)	54 (42%)	170
Total	147 (100%)	128 (100%)	275

A = Active immunization with 0.1 c.cm. of A.P.T.

A+P = Ditto, plus 350 to 500 units of antitoxin.

$\chi^2 = 68.089$. $P < 0.000001$.

As in Table II, it is seen that the proportion of sera containing 1/500 unit or more of antitoxin was considerably higher in the A+P than in the A group—58% contrasted with 21%. And again as in Table II, more sera in the A group had a relatively higher antitoxin content than in the A+P group. The higher proportion, however, of sera in the A+P group containing antitoxin is shown to be significant by the χ^2 test.

In Table V are set out the antitoxin titres in Sets TC, O1, O2, C1, C2, and S at an average of 8½ weeks after the second dose of A.P.T. As in Table III, the proportion of sera in Group A containing 1/50 unit or more of antitoxin is higher than in Group A+P—65% as compared with 50%—but the difference is not so great, and the lower value of χ^2 renders this difference of far less significance.

Judged by the percentage values the difference between the two groups in Table IV is slightly less than in Table II; this may perhaps be due to the fact that the average time of bleeding of the students recorded in Table IV was later than that in Table II. This, in turn, might be expected (a) to lead to a

TABLE V.—Turner's Court, Oxford, Cambridge, and Sheffield Students: Sets TC, O1, O2, C1, C2, and S. Antitoxin Titres 8 to 12 Weeks (average 8.7 Weeks) after Second Immunizing Dose

Antitoxin Units per c.cm. of Serum	A	A+P	Total
	No.	No.	
Good response: 1/50 or more ..	91 (65%)	59 (50%)	150
Fair response: 1/100 to 1/500 ..	36 (26%)	38 (32%)	74
Poor or no response: 1/1,000 or less ..	13 (9%)	21 (18%)	34
Total	140 (100%)	118 (100%)	258

A = Active immunization with 0.1 c.cm. and 0.3 c.cm. A.P.T. at 4 to 10 weeks' interval (average 4.4 weeks).

A+P = Ditto, plus 350 to 500 units of antitoxin at time of first injection.

$\chi^2 = 6.938$. $P = 0.031$.

greater excretion of the antitoxin inoculated into the A+P group, and (b), on the assumption that serum delays the antitoxin response, to reveal the beginning of antitoxin production resulting from the first dose of A.P.T. in Group A.

Again, the difference between the two groups in Table V is less than in Table III; this may be related to the greater length of time that elapsed between the second immunizing dose and the final bleeding of the students recorded in Table V. If it is assumed that the serum delayed but did not prevent the antitoxin response of subjects in the A+P group, this would have allowed time for the formation of antitoxin in an amount more nearly approaching that of subjects in Group A. These suggestions are admittedly hypothetical, but evidence will now be brought to show that they are not without foundation.

It may be noted that the results in Tables II to V are weighted to some extent in favour of the A group by the circumstance that 7 students in the A group are known to have been immunized previously, as against only 3 in the A+P group.

RATE OF DISAPPEARANCE OF INJECTED ANTITOXIN FROM THE CIRCULATION

At Cambridge 12 of the students in the A+P group, each of whom had received 0.1 c.cm. of A.P.T. and 500 units of antitoxin, and bled at weekly intervals for 4 weeks so as to determine the antitoxin content of their serum. The results are given in Table VI.

TABLE VI.—Fall in Antitoxin Content of Serum within 4 Weeks of Inoculation of 0.1 c.cm. of A.P.T. + 500 Units of Antidiphtheria Serum. Part of Set C2

Antitoxin Units per c.cm. of Serum	1 Week	2 Weeks	3 Weeks	4 Weeks
1/25 or greater	4	1	1	1
1/50	6	0	0	0
1/100	2	10	1	1
1/250	0	0	10	0
1/500	0	1	0	5
1/1,000	0	0	0	2
< 1/1,000	0	0	0	3
Total	12	12	12	12

It will be seen that, roughly speaking, after 1 week the commonest titre was about 1/50 unit, after 2 weeks about 1/100 unit, after three weeks about 1/250 unit, and after 4 weeks between 1/500 and 1/1,000 unit. Apart from one student who had been immunized three to four years previously and whose titre rose from 1/25 unit after 1 week to 1/5 unit after 2 weeks, it would appear that the antitoxin content of the serum fell progressively and that there was no obvious evidence of active formation of fresh antitoxin. At 4 weeks 75% still had 1/1,000 unit or more per c.cm. of serum.

These results may be usefully compared with those in Table II. After 4 weeks only 3 of the 94 subjects in the A+P group had an antitoxin titre of 1/50 unit or more, suggesting the formation of fresh antitoxin. The majority had a titre of between 1/100 and 1/1,000 unit, a total of 79%* having 1/1,000 unit or more. Since only 34%* of those in the A group had 1/1,000 unit or more, it is difficult to avoid the conclusion that the antitoxin present in the great majority of the A+P sera was residual antitoxin.

* These figures are obtained from the individual protocols

This conclusion is further borne out by comparison of the results in Table VI with those of previous workers who have studied the rate of disappearance of injected antitoxin from the circulation. Most observations of this type appear to have been made on animals, but some, such as those by Ramon, Debré, and Bernard (1933) and E. Madsen (1936), were made on diphtheria patients who were injected with varying quantities of antitoxin for therapeutic purposes. Others, such as those by Frey and Schmid (1939), were carried out, like our own, on subjects who received active and passive immunization simultaneously. Smith (1907) seems to have been one of the few who made observations that were not complicated either by the presence of active disease in the subject or by simultaneous inoculation of an immunizing antigen; unfortunately his observations were limited to those on a single adult male.

Without discussing the results of these workers in detail, attention may be drawn to the work of T. Madsen (1902, 1923), who found that the rate of disappearance of antibody from the blood of passively immunized persons could be represented by an equation which was not unlike that of a monomolecular reaction. That is to say, a curve drawn by plotting the absolute values of antitoxin per c.c.m. of blood against time fell rapidly to start with and then flattened out till it was almost parallel with the axis of abscissae. The rate of disappearance, however, varied not only with the amount of antitoxin injected but with the individual person studied. This second variable made it impossible to predict from the behaviour of one person what the rate of disappearance of antitoxin would be in another person. These conclusions of T. Madsen's were borne out by the work of E. Madsen (1936), and there is no reason to doubt their general validity.

The possession of a constant by each individual makes it difficult to compare the results of different workers with each other and with our own. When, in addition to this, other factors may have influenced the result, such as previous immunization against diphtheria by natural or artificial means, as in some of the subjects studied by Ramon and his colleagues, it is clearly impossible within a short compass to make any statistical comparison between the recorded figures of different workers. A general review of these figures, however, shows that when horse serum containing antitoxin is injected into the body a large proportion of it is excreted within the first two or three weeks, but that a small proportion generally persists for at least four weeks.

Perhaps the nearest parallel to our own figures are those given by Frey and Schmid (1939), who inoculated healthy children with 1,000 to 2,000 units of antitoxin intramuscularly together with 1 c.c.m. of A.P.T. subcutaneously. All the children, it may be noted, had less than 0.0005 unit of antitoxin per c.c.m. in their blood serum at the time of injection. In every child inoculated with antitoxic horse serum the titre fell from a maximum of 0.45 to 1.8 units after 3 days to a figure varying from 0.007 to 0.03 unit after 28 days. In none of them was there any evidence of a rise in the titre suggestive of active antibody formation.

Our own figures, it will be remembered, showed the presence of about 0.002 unit per c.c.m. after 28 days. Considering that the amount of antitoxin inoculated into our students was only a half to a quarter of that used by Frey and Schmid, the rate of disappearance of antitoxin from the circulation appears to have been much the same in both groups. These figures are in general agreement with those obtained by Smith (1907) on a healthy adult, and by E. Madsen (1936) on diphtheria patients, whose curves were so regular as to exclude almost any possibility of active antitoxin formation within four weeks.

It may therefore be concluded that in healthy students having less than 1/1,000 unit of antitoxin per c.c.m. of serum and inoculated with 0.1 c.c.m. of A.P.T. and 500 units of anti-diphtheria serum, any antitoxin found in the blood during the succeeding four weeks is probably residual antitoxin. Occasional students who have had previous experience of the diphtheria bacillus, directly or indirectly, may respond rapidly by the formation of considerable amounts of antitoxin, but apart from these there is little evidence to suggest that when given along with 500 units of antitoxic serum 0.1 c.c.m. of A.P.T. is sufficient to stimulate the formation within four weeks of more than minimal quantities of antibody.

RATE OF FORMATION OF ANTITOXIN IN THE A AND A+P GROUPS

From the figures just recorded it is evident that, with the immunizing doses used, fresh antitoxin, except in minimal quantities, is unlikely to be detected within 4 weeks either in those given active immunization alone or in those given combined active and passive immunization. A study of Table III, however, shows that 8 weeks after the second immunizing dose most of the subjects had formed fresh antitoxin. Of those in the A group 88%, and of those in the A+P group 71% had produced more than 1/1,000 unit of antitoxin per c.c.m. of serum. The question arises whether the poorer response of those in the A+P group was due to real inhibition of antitoxin formation as the result of the simultaneous injection of serum with the first dose of A.P.T., or merely to delay in its formation. To answer this question antitoxin titrations were made at Cambridge on the two groups of students at different times after the second dose of A.P.T.

In the first set of students, C1, the third bleeding was made 6 instead of 8 weeks after the second dose of A.P.T., and a fourth bleeding was made 12 weeks after the second dose of A.P.T. The summarized results are given in Table VII.

TABLE VII.—*Change in Antitoxin Content of Serum between 6 Weeks and 12 Weeks after Second Immunizing Dose. Part of Set C1*

Antitoxin Units per c.c.m. of Serum	A		A+P		Total Observations
	6 Weeks	12 Weeks	6 Weeks	12 Weeks	
1/2 to 2	2	2	1	0	5
1/5 to 1/25	4	4	2	6	16
1/50 to 1/250	6	8	11	10	35
1/500 to 1/1,000	2	1	3	4	10
< 1/1,000	1	0	3	0	4
Total	15	15	20	20	70
Rise		7		14	
Fall		3		2	
No change		5		4	

A = Active immunization with 0.1 c.c.m. and 0.3 c.c.m. A.P.T. at 4 weeks' interval.

A+P = Ditto, plus 400 units of antitoxin at time of first injection.

The figures in the last three rows are obtained from the individual protocols.

It will be noticed that in the A group there was a slight increase in the titre of antitoxin at 12 weeks, 7 sera showing a rise, 3 a fall, and 5 no change. In the A+P group, however, 14 showed a rise, only 2 a fall, and 4 no change. The suggestion is therefore very strong that the rate of formation of antitoxin is slower in the A+P than in the A group. It looks also as if in the A group the peak of antitoxin production is probably reached somewhere between 6 and 12 weeks.

In a second set of students, part of C2, antitoxin titrations were made 8 and 12 weeks after the second dose of A.P.T. The results are shown in Table VIII.

TABLE VIII.—*Change in Antitoxin Content of Serum between 8 Weeks and 12 Weeks after Second Immunizing Dose. Part of Set C2*

Antitoxin Units per c.c.m. of Serum	A		A+P		Total Observations
	8 Weeks	12 Weeks	8 Weeks	12 Weeks	
1/2 to 2	2	2	1	1	6
1/5 to 1/25	24	23	5	8	60
1/50 to 1/250	13	13	17	25	68
1/500 to 1/1,000	7	9	12	9	37
< 1/1,000	2	1	11	3	17
Total	48	48	46	46	188
Rise		8		28	
Fall		19		4	
No change		21		14	

A = Active immunization with 0.1 c.c.m. and 0.3 c.c.m. of A.P.T. at 4 weeks' interval.

A+P = Ditto, plus 500 units of antitoxin at time of first injection.

The figures in the last three rows are obtained from the individual protocols.

The difference between the two groups is even more striking than in Table VII; of the A group only 8 sera showed a rise, whereas 19 showed a fall and 21 no change. In the A+P group the corresponding figures were 28, 4, and 14. The two conclusions reached from a study of Table VII are therefore considerably strengthened.

FOUR CASES OF PNEUMOCOCCAL PERITONITIS

BY

CHARLES NOON, F.R.C.S.

Group Adviser, E.M.S.; Surgeon, Norfolk and Norwich Hospital

Acute pneumococcal peritonitis is an uncommon disease. The use of surgery with the administration of sulphapyridine illustrates an advance which has taken place in the treatment of this type of peritonitis during the last few years. Before the introduction of Felton's type antipneumococcal serum and sulphapyridine, pneumococcal peritonitis was an extremely fatal disease. Following the administration of the serum a certain number of these patients got well, and there is a distinct hope that the introduction of sulphapyridine will further reduce the mortality.

When I was house-surgeon to Mr. H. J. (now Sir Holburt) Waring I was able to collect, with Mr. A. L. Moreton, 6 cases of this disease that had been admitted to Mr. Waring's wards, all of which were fatal (Noon and Moreton, 1912). Similar results were recorded by other observers.

Rischbieth (1911) gives statistics of 57 cases of pneumococcal peritonitis. Of these, 45 were cases of acute general peritonitis, with a mortality of 100%.

Sir Dyce Duckworth and Mr. H. Marsh (1904) recorded a case successfully treated by operation and antipneumococcal serum. They refer to other cases, none of which, however, recovered. Up till 1932 further cases of acute pneumococcal peritonitis came under my care, but all proved fatal. Since 1932 I have had 4 cases, all of which have recovered. These seem to be of sufficient interest to justify publication. Three of them were treated by laparotomy with drainage of the pelvic cavity and intramuscular injections of antipneumococcal serum, Felton's type, and the fourth by laparotomy with drainage and the administration of sulphapyridine. While, however, the first three gave rise to considerable anxiety and recovered only after a long illness, the fourth caused no anxiety and made a rapid recovery.

Case I

Pneumococcal peritonitis. Laparotomy; protracted pyrexia. Recovery

A schoolgirl aged 8 was admitted to the Norfolk and Norwich Hospital on April 6, 1932, complaining of severe abdominal pain with vomiting. On the day before admission she was said to have received a severe blow in the abdomen when returning from school.

On admission she looked ill; her temperature was 101.5°, and the pulse rate 124. The abdomen was distended, rigid, and tender. A diagnosis of acute peritonitis was made. The abdomen was opened, revealing acutely inflamed intestine and a large collection of thick yellow pus in the pelvis. The appendix, which was not inflamed, was removed. The abdomen was closed, with drainage. Examination of pus showed a pure culture of pneumococcus, Type II.

She was treated by injections of antipneumococcal serum, Types I and II (Parke, Davis), 10,000 units being given daily from April 7 to 12. She made satisfactory progress, and was discharged from hospital in good health on June 4.

Case II

Acute pneumococcal peritonitis. Laparotomy; double empyema; right side of chest drained; left side aspirated. Complete recovery

A school teacher aged 23 was admitted to a nursing home on June 5, 1933, complaining of severe abdominal pain and

diarrhoea. Temperature 104°; pulse rate 120. She had been ill for four days.

On examination she looked ill and anxious; her temperature was 102.8° and pulse 140. The abdomen was distended, rigid, and tender. An abdominal operation scar showed that the appendix had been removed some years ago. A provisional diagnosis of acute pneumococcal peritonitis was made. The abdomen was opened and the peritoneal covers of the intestines were found to be red and inflamed. There were some flecks of lymph and some flocculent inodorous pus. The latter was mopped up and the abdomen closed with drainage. An intramuscular injection of 20,000 units of antipneumococcal serum was given, with a further 10,000 units on June 6 and 10. On July 3 the blood leucocyte count was 28,400 per c.mm. Signs at the base of the right lung continued to increase. On July 7 a right-sided empyema was drained by the resection of a piece of rib. Improvement followed this operation. After two weeks later signs began to develop at the base of the left lung, and purulent fluid was aspirated. Accumulation of fluid did not recur. The empyema wound on the right side of the chest continued to discharge. The patient left the nursing home on August 14, after a very severe illness lasting ten weeks. She gained weight, and finally recovered completely.

Case III

Acute pneumococcal peritonitis. Laparotomy; protracted pyrexia. Recovery

A schoolgirl aged 9 was admitted to the Norfolk and Norwich Hospital on March 12, 1937, complaining of acute abdominal pain and vomiting.

On examination she looked ill; her temperature was 102° and pulse rate 128. The abdomen was not distended, but was rigid and tender. A diagnosis of acute peritonitis was made. The abdomen was opened, and the small intestine was seen to be covered with flaky lymph. The appendix, which was not inflamed, was removed and the abdomen closed with drainage. Examination of pus revealed pneumococci. Blood culture following the operation grew pneumococci. The patient was given 10,000 units of antipneumococcal serum intramuscularly for three days following operation, and made gradual progress towards recovery, being discharged on May 29.

Case IV

Acute pneumococcal peritonitis. Laparotomy; post-operative treatment with sulphapyridine

A female laundry worker aged 18 was admitted to the Norfolk and Norwich Hospital on October 2, 1940, complaining of acute abdominal pain, vomiting, and diarrhoea. She had been ill for three days.

On examination she looked anxious; her face was flushed and the tongue rather red and dry. The temperature was 101° and the pulse 160. The abdomen was somewhat distended with marked tenderness below the navel and to the right of the midline. A diagnosis of general peritonitis, cause uncertain, was made. The abdomen was opened on the day of admission. The peritoneal surface of the intestines was red and inflamed. There were also some inflamed and enlarged mesenteric glands in the region of the caecum. The appendix was not inflamed but was removed. There was some inodorous yellowish-green pus in the pelvis; this was removed. The abdomen was closed, with pelvic drainage. Examination of the pus revealed pneumococci.

The pneumococcal infection was treated with sulphapyridine given partly by mouth and partly intravenously. Between October 2 and 6 36 grammes were administered as follows: First day, 4 grammes; second day, 10 grammes; third day, 10 grammes; fifth day, 12 grammes; sixth day, 2 grammes. The dosage was determined by the clinical signs of the severity of the infection. The wound continued to discharge until November 1, but by November 6 it was healed. The patient's local and general condition continued to be satisfactory, and she was able to leave hospital.

CUTANEOUS ANTHRAX TREATED BY ARSENICALS AND SULPHAPYRIDINE

BY

IAN MACKENZIE DAVIDSON, M.B., Ch.B.

Surgical Registrar, Cumberland Infirmary, Carlisle

Cases of cutaneous anthrax are rare, and few have been recorded in which modern chemotherapy was used. The following case is therefore placed on record.

Case Report

The patient, a gardener aged 53, was admitted to hospital on January 25, 1941. Some years previously he had had a succession of small boils, but had been free of these for four years. A week before admission he noticed a small pimple on the back of his neck which at first looked and felt like the early stages of a boil. The evening before admission the pimple quickly extended and the surrounding area swelled rapidly. There was not the severe pain he had experienced with previous boils. During the next twenty-four hours the swelling extended to each

the second, fourth, and sixth days after admission were: 11,000, 16,800, and 9,200 per c.mm. respectively.

The condition of the lesion had not altered to any marked degree on the 27th (Fig. 2), but the temperature and the pulse rate were normal and remained so until the patient left hospital.

By the 30th the patient looked and felt much better, and there had been no toxic effects following the administration of sulphapyridine. The oedema had very largely subsided, the original lesion being a bluish-black scab, the edges of which were beginning to separate. Only with difficulty could the pathologist find material for the platinum loop. Below the original lesion there was a large flat blood-stained blister (Eurich, 1933) containing gelatinous sanious material (Fig. 3). Cultures taken from the scar and blister at this stage yielded abundant growths of *Staphylococcus aureus*, but both were negative for *Bacillus anthracis*. By February 2 the original lesion was still drier. The central eschar was further separated, and was surrounded by a pale slightly raised ring.

The patient was discharged on February 7. There was only slight residual induration from the occiput to the interscapular region behind, and the dry scab had almost completely separated, exposing a healed eschar. The blood blister had by this

FIG. 1.

FIG. 1.—Photograph taken two days after admission, showing the oedema described in the text.

FIG. 2.

FIG. 2.—Photograph of the lesion two days after admission.

FIG. 3.

FIG. 3.—Photograph of the lesion on the sixth day after admission.

side of the neck, and he vomited on several occasions. His doctor suspected anthrax and referred him for institutional treatment.

On admission, late in the evening, the patient was found to have a blood-stained vesicular lesion about an inch in diameter on the back of his neck. The vesicle was not tense and the overlying cuticle was crenated. There was solid oedema of the surrounding parts, extending to the interscapular region, to the occiput, and to the lateral aspect of the neck in front of the sternomastoids, the swelling being very noticeable on viewing the patient from the front (Fig. 1). His temperature was 102.4° F. and the pulse rate 108. His tongue was moist but slightly furred. Despite the alarming appearance of the lesion the patient did not look markedly toxic or distressed. There was nothing of note in the mouth, heart, and lungs; the spleen was not enlarged, and there was no albumin in the urine.

Shortly after admission smears and cultures were made from the fluid beneath the crenated surface of the lesion, and an examination of the straight films showed Gram-positive cocci and Gram-negative bacilli in abundance and a few rod-shaped Gram-positive organisms. The culture after twelve hours showed the typical "dried cotton-wool" appearance of anthrax, and stained slides from culture were typical of the anthrax bacillus.

On the morning of January 26 a full course of sulphapyridine was started, with 2 grammes as an initial dose, followed by 1 gramme four-hourly for forty-eight hours, and then 1 gramme three times a day for thirty-six hours. Later he was given 0.5 gramme three times a day for four days, making a total dosage of 24.5 grammes. On the day after admission 10 c.cm. of Selavo's anti-anthrax serum was given subcutaneously into the abdominal wall. Arsenic was also given, intravenously, in the form of neokharsivan in doses of 0.6 gramme on the second, third, and sixth days after admission. Leucocyte counts on

time completely disappeared. When seen a month after discharge the patient was quite well; there was a healed area to mark the site of the original lesion, with some little induration, especially on the right side.

The diagnosis of anthrax was confirmed by inoculation of a guinea-pig, which died within forty-eight hours, the heart blood and spleen giving cultures positive for anthrax.

Commentary

The situation of the lesion and the occupation of the patient are interesting but not unique, as there was a report in the *Lancet* (1938, I, 1417) of an inquest on June 4, 1938, on a market gardener aged 30 who died in the Manchester Royal Infirmary from anthrax septicaemia following a lesion on the back of the neck. The jury returned a verdict of death by misadventure, but added a rider that death had been caused by handling artificial manure.

Investigations so far have failed to reveal the source of anthrax in the case under consideration, but the supposition is that the patient's hands were infected by some article with which he had been working, and so had infected the small lesion on the neck direct or through the agency of the coat collar. Samples of vine and plant manure, bone meal, and bird food mixture containing dried meat and foreign flies, with which the patient had been working, were cultured direct on to media and subcultured, but nothing suggesting anthrax was discovered. Further cultures were made after subjecting samples to 3% caustic potash, and others to boiling, with the object of reducing ordinary micro-organisms, but without success. Farmyard manure with which he had also been working came from

a farm where there had been no case of anthrax among the animals.

The low incidence of anthrax is indicated by infectious diseases returns. According to the annual report of the Chief Inspector of Factories and Workshops only 30 cases were notified in 1936, and the average mortality in the cutaneous form over a period of thirty years has been from 3.3% to 24.3% (Legge, 1934), hence the importance of recording individual cases in order to assess the value of therapeutic measures.

The question of sulphanilamide therapy in anthrax has recently been brought to the forefront by the work of Cruickshank (1939), Bonnar (1940), and others, and it was intended at the outset to treat the case by sulphapyridine alone in order to attempt to support the contention that cases of cutaneous anthrax could be successfully treated by this means (Thrower, 1941). "As the conditions essential to clinical trial are almost impossible to fulfil," and one has to consider treatment primarily in the interests of the patient as his life is at stake; the line of treatment adopted included arsenicals, which the literature appears to indicate as being of distinct value, and also Sclavo's serum. The latter can probably be disregarded on account of the small quantity given, the available supply being limited.

Osgood, Joski, and Brownlee (1940) have shown that arsenic and sulphathiazole form the most effective combination against *Staph. aureus* in bone-marrow cultures, and this suggests that the combination of arsenic and sulphanilamide may be worthy of further clinical trial in the treatment of cutaneous anthrax.

My thanks are due to Mr. J. N. J. Hartley, under whose care this case was treated, for permission to publish this paper, and to Dr. J. Steven Faulds, who confirmed the diagnosis by film culture, and guinea-pig inoculation, and by whom the photographs were taken.

DARK ADAPTATION AND MINERS' NYSTAGMUS

BY

IAN CAMPBELL, M.B., Ch.B.

The association between failure of dark adaptation, or night-blindness, and miners' nystagmus has long been recognized, and has been commented upon by many observers. C. Turner Thackrah (1831), writing of colliers, remarks: "Their eyes . . . are intolerant of full light." Court (1891) states: "A definition of the disease [i.e., miners' nystagmus] should include night-blindness, nystagmus . . . because these symptoms all occur together in miners working with the inferior light." The First Report of the Miners' Nystagmus Committee, 1922, states: "This failure of dark adaptation, or night-blindness, is undoubtedly one of the most characteristic symptoms of the disease"; whilst Roche (1931) states: "One of the first symptoms of nystagmus is deficient vision at twilight. All miners suffering from nystagmus complain of twilight blindness."

That hemeralopia is found in the "pre-nystagmus" stage is observed in the Departmental Committee's Report on the Workmen's Compensation Acts, 1938: ". . . there are some men who ultimately develop oscillations of such extent as to become cases of miners' nystagmus who have complained of earlier subjective symptoms such as mal-projection,

intolerance of light from lamps of other workers, difficulty of seeing on entering the mine workings or leaving them."

Weekers in 1910 even suggested that failure of dark adaptation was the cause of miners' nystagmus (First Report of Miners' Nystagmus Committee, 1922). Oglesby (1880) stated: "I was at first impressed with the idea that pigmentation of the retina lay at the root of the mischief," but discarded his theory on negative ophthalmoscopic findings. Ohm in 1916 considered that "disturbances of dark adaptation have proved factors which predispose to nystagmus" (First Report of Miners' Nystagmus Committee, 1922).

Though most observers have noted the occurrence of night-blindness in miners' nystagmus, few have suggested an explanation of it. Jeaffreson (1887) states: "The interference [i.e., obstruction of the blood flow through the vertebral arteries] with the nutrition of the visual centres may be one of the chief features in the production of hemeralopia, which is almost always present." Roche (1931) suggests that it is probably due to two causes: (1) "The stratum pigmentum produces visual purple. As a result of continuous over-production these cells become defective and nearly cease to secrete altogether, or they secrete a visual purple which is too diluted and ceases to stimulate the rods on exposure to light." Or: (2) "Normally, several rods have only one central nerve connexion, and continued use provokes fatigue, and consequently poor transmission of impulses." The Third Report of the Miners' Nystagmus Committee, 1932, on the other hand, considers the night-blindness of miners' nystagmus to be one of the psychoneurotic manifestations of this disease.

Association of Diet and Miners' Nystagmus

Recent work done on the association between deficiency of vitamin A and night-blindness leads me to consider the association of diet and miners' nystagmus. On this subject Martin (1920) believes that "exhaustion, due to want of food and prolonged physical strain, is the most important, most effective predisposing cause of the disease"; while Stephens (1932) considers the nature of the miners' food all-important. His views he expresses thus: "Since the introduction of tinned foods and preserved meats, the feeding of the collier is much below what it used to be. Formerly the Welsh collier used to live on good home-grown produce, with milk, eggs, and cheese . . . [italics mine]. To-day ill-feeding tinned foods are the chief features of the household board in a large number of homes, and it is from these homes that the army of nystagmus patients is recruited."

Investigations of the diet of miners in this area show that with the improvement in housing conditions, giving most miners a garden of their own, in which they are keenly interested and proficient, the supply of vitamin A (or its precursor) from green vegetables, carrots, etc., is in the summer months plentiful, but in the winter months, when this home-grown source is at a minimum, the intake of vitamin A is greatly reduced. It is just at this time also that the seasonal variation in the vitamin A value of dairy produce manifests itself. As stated in *The Vitamins* (Crookes Laboratories), "the vitamin A value of milk, butter, and eggs tends to be at its lowest in the early part of the year." Further, when the intake of vitamin A is at its lowest the demand for it, in the interest of vision, is at its highest, for the miner in the dark winter months has a greater need for dark adaptation apart from the time actually spent below ground.

It is interesting to note that many observers have found miners' nystagmus to be more prevalent in the dark winter months. The following table, from the First Report of the

Miners' Nystagmus Committee, supports this view. For the last entry I am indebted to Mr. W. E. Gillhespy. I have converted the numbers into percentages.

Cases Arranged according to the Quarter of the Year in which Failure Took Place

	No. of Cases	1st	2nd	3rd	4th
Dransart and Famechon ..	201	33.33%	17.91%	17.41%	31.34%
Olum ..	521	30.51%	26.29%	20.34%	22.64%
Llewellyn ..	1,649	34.26%	18.79%	22.61%	24.36%
Yorkshire Coal Owners' Indemnity Society (1930-9 inclusive)	1,647	30.44%	26.06%	22.19%	21.24%

These figures in each case show that more failures occur in the first quarter of the year.

Deficient Illumination the Essential Factor

It is now generally recognized that the chief factor in miners' nystagmus is deficient illumination, and that "during all the years when the miner is working at the coal face his macular vision is in more or less complete abeyance" (Departmental Committee's Report on the Workmen's Compensation Acts, 1938). This means that vision is mediated by the rod elements of the retinal periphery, calling for an adequate secretion of visual purple, which, in turn, demands an adequate blood supply of vitamin A.

The following experiment was carried out with the use of Crookes's dark-adaptation tester (for description of tester see *Trans. ophthalm. Soc.*, 1938, 58, 103). Three people living on an ordinary mixed diet were tested and an average curve taken. This was accepted as the normal for the instrument used. Ten miners, all working, were selected at random apart from being of a "nystagmus age." The average age for the group was 38, and the average number of years worked underground 23. An average curve was plotted for this group. Three were selected from this group, one of whom, it was noted, had oscillations in daylight, at the horizontal level, before exercises. These were put on intensive vitamin A treatment until each was able to see the arrow at the lowest finger-post position used. An average curve was then plotted for this group. (See Graph. At finger-post position 30 and 10, in Curve B, two and five

0.047, 0.028, 0.0093, 0.0047 millifoot candle respectively. The results are shown in the following table:

Table showing Results of Dark-adaptation Tests (Time in Minutes)

Case	Age	Occupation	Finger-post Position									
			Neutral Glass					Dark Glass				
			75	50	30	10	5	30	10	5		
3 Normals:												
A	38	Housewife	3.25	5.45	7.40	9.40	13.50	14.20	16.20	17.35		
B	16	Clerk	3.35	6	6.15	9.25	11.20	13.20	14.55	18.20		
C	31	School teacher	2.55	3.45	3.57	4.18	6.10	6.50	10.30	24.25		
10 Colliers:												
1	35	Collier	9.15	9.30	12.10	13.55	24.30	27.20	—*	—*		
2	36	"	7.55	9.03	9.30	12.40	35.10	36.30	—*	—*

8	42	Haulier	6.30	8.10	8.25	12.55	13.45	39.30	—*	—*		
9	29	Collier	5.45	6.55	8.35	10.55	15.25	16.30	34.55	—*		
10	40	"	7.05	7.40	8.25	12.50	15.10	16.15	—*	—*		
3 Colliers after Treatment:												
1	35	Collier	3.10	5.02	5.32	7.10	15.10	16.10	20.20	27.10		
2	36	"	5.30	7.10	7.45	11.10	13.05	17.20	20.50	38.50		
9	29	"	3.15	4.10	5.30	9.20	11.50	12.25	15.30	33.10		
Average for 3 Normals			3.18	5.10	5.57	7.47	10.16	11.30	13.55	20.06		
" " 10 Colliers			7.47	8.41	9.41	12.17	19.35	23.49*	34.55*			
" " 3 Colliers after treatment			4.05	5.27	6.15	9.13	13.06	15.18	18.53	34.43		

The average results are shown in the graph.

Cases A and B each had for two days before the test 4 capsules vitamin A (oral) a day. Case C neither had, nor was taking, any vitamin preparation.

The times marked * signify that the arrow was not seen up to 40 minutes. To estimate an average time, the dark glass being used and the finger-post at 30 and 10, those failing to see the arrow after 40 minutes were counted as having seen it at 40 minutes. The last two average figures given should therefore be greater than shown.

Case 9 results were given after taking 6 capsules vitamin A (oral) Crookes a day for seven days: Case 2 results after 3 capsules a day for three days followed by 6 capsules a day for a further nine days: Case 1 readings were given after 6 capsules a day for 27 days. He was examined weekly, and, as mentioned, had the oscillations of miners' nystagmus in daylight, at the horizontal level, before exercises.

These observations show that in the group of miners selected a deficiency of vitamin A, as demonstrable by the dark-adaptation test, was present, and by the administration of vitamin A over a limited period the power of dark adaptation was considerably improved.

As the miner depends for his working vision, and safety, on his retina periphery, and must continually adapt to low illuminations and sudden changes in light intensity, it seems desirable that he should receive an optimum supply of vitamin A. This need is further enhanced, in my opinion, by the peculiar tendency of the collier to develop miners' nystagmus.

I am indebted to Dr. Edith Hatherley for her useful advice, and to Crookes Laboratories for the use of a dark-adaptation tester.

Curve A = Average 3 normals.

Curve B = Average 10 colliers.

Curve C = Average 3 colliers after additional vitamin A.

colliers respectively were unable to see the arrow after 40 minutes. To arrive at an average time for the ten, these were included as having seen the arrow at 40 minutes, so that, properly, this curve should go further to the right.)

The same technique was followed in each case: half an hour seated in the dark, four minutes' "bleaching," and up to 40 minutes' examination. All the tests were done in January or February of this year, and between 8 and 10.30 p.m. The finger-post positions used were: light neutral glass, 75, 50, 30, 10, 5; dark glass, 30, 10, 5—corresponding to an intensity of illumination of 0.7, 0.47, 0.28, 0.093,

S. Wolff (*Ann. Pediatr.*, 1941, 4, 155) records an epidemic of streptococcal disease, apparently unparalleled in the literature, which occurred in the Children's Hospital at Eisenach. Of eight children affected two died. All the patients fell ill on the same day (September 26, 1935) and almost at the same hour. Seven started with a throat infection. The course was identical, especially as regards the temperature. Sulphanilamide was very effective except in the two fatal cases. The cause of the outbreak could not be discovered.

Medical Memoranda

Encephalomyelitis in a Case of Pink Disease

Although the symptoms and signs of pink disease are well known the cause is not yet established. Rocaz, however (*Pink Disease*, 1933, p. 129, supports the idea of an encephalitis due to a neurotropic virus. When it is considered that outbreaks of the disease take the form of individual cases scattered through any one area, the disease certainly does resemble poliomyelitis and polio-encephalitis in some respects. There is, however, little evidence of direct transmission from one child to another, and it is not usual for two members of a family to be affected. Another curious point to note is that the outbreaks are often limited to industrial areas, and occur among the children of the artisan class, although there is no observable relation to poverty. It is notable, too, that the disease only affects young children. The following case is interesting in that the necropsy supports the idea that an encephalomyelitic lesion was the cause of the symptoms and signs.

CASE REPORT

A child aged 1 year, one of a family of seven children, came from an industrial area; the father was a meter collector earning £2 18s. a week. The child had had infantile eczema for six months, and had been losing weight for the past fortnight. He had been breast-fed, but weaned on to cows' milk, gravy, potatoes, milk puddings, etc. Had been suffering from diarrhoea for two weeks, with green foul-smelling stools. Had a cough for a week; no vomiting. Also suffering from insomnia, and profuse sweating especially in the head region.

Condition on Admission.—The child was somewhat dehydrated, and showed great hypotonia of the muscles, with flaccidity and wasting. There was a rash, typical of pink disease, on the trunk, face, and legs. The child was irritable, scratching and rubbing the affected areas continually. The hands and feet were cold, pink, and shining. There was some desquamation. The general appearance suggested a case of pink disease of considerable severity and duration. Chest: poor resonance at both bases, with fine rales. Tongue furred. Abdomen retracted.

The illness ran through five weeks, with extreme asthenia and insomnia. Later the case gave a clinical picture of pink disease of a very severe type. Death took place from general debility and cardiac failure.

Post-mortem Examination.—Dr. William Susman reported as follows: Body extremely emaciated. Pericardium: complete absence of fat; is of a greyish colour due to toxins. Heart: myocardium, rather pale but firm; tricuspid valve, 1 finger; pulmonary valve, healthy; mitral valve, 1 finger, healthy; aortic valve, healthy. Right lung: posterior aspect of upper and lower lobe shows appreciable amount of haemorrhage. Left lung: posterior aspect of lower lobe has peripheral zone of haemorrhage about 2 cm. in depth which extends the whole length of the lobe. Microscopically a confluent bronchopneumonia. Air passages: some frothy mucus present. Alimentary passages: oesophagus, nothing abnormal; stomach, passive congestion; small intestine, nine agonal intussusceptions; large intestine, nothing abnormal. Liver, intense passive congestion. Gall-bladder healthy. Common bile duct patent. Pancreas congested. Spleen, nothing abnormal. Thyroid atrophied. Thymus very atrophic. Adrenals healthy. Right kidney and left kidney, fairly pronounced degree of passive congestion. Pia arachnoid acutely congested. Brain: grey matter throughout is acutely congested; in the basal nuclei the red appearance has a greyish mottled background; the grey matter of the pons and medulla is also acutely congested; the appearances are those of an acute encephalomyelitis.

The microscopical report was as follows: Abdominal sympathetic chains: there is some recent degeneration in the ganglion cells and in some nerves; surrounding muscle tissue that has been included in the section shows some scattered foci of subacute myositis. Cerebrum: there is a most intense and generalized acute congestion associated with a widely disseminated acute encephalomyelitis. The lesions are most pro-

nounced in the basal ganglia. The perivascular region of many arteries shows sclerosis and in some a pronounced degree of fibrosis. The cerebellum, pons, medulla, and spinal cord are similarly affected but to a lesser degree. Many nerves show parenchymatous degeneration.

COMMENT

The presence of a severe encephalomyelitis of a standing which corresponds to the duration of the illness due to pink disease is important as indicating the likelihood of a virus infection. The history of a gastro-intestinal infection is noteworthy, and in my experience is not uncommon.

St. Mary's Hospitals, Manchester.

An Unusual Sequel to Blood Transfusion

The following case, in which attacks of insanity followed blood transfusions, may be considered worth recording.

CASE HISTORY

A married woman aged 41, in extremis with extensive carcinoma of the cervix, was admitted to hospital for radium treatment under Mr. Ellis, by whose permission the case is submitted. Her subsequent pulse rate varied between 90 and 125, respirations between 24 and 31, and temperature between 98° and 102°, remaining normal for the whole week before her death from massive collapse of the lungs. Pyuria was present throughout. Sulphanilamide and iron were administered intermittently. Blood examination on admission—Group O (IV)—showed 22% haemoglobin, 1,800,000 red cells, 16,000 white cells, colour index 0.61, with anisocytosis and poikilocytosis. The blood urea was 43 mg. per 100 c.cm. Three days after admission she received by drip two pints of citrated Group O blood (one day old), with about half a pint of saline, over six hours. Her condition afterwards was good and no rigor occurred. During the next week abdominal discomfort became more pronounced, and a kaolin poultice was applied. The haemoglobin four days after transfusion was 42%. A projected cervical diathermy was abandoned ten days after transfusion on account of her poor condition. Sixteen days after the transfusion radium was inserted into the growth under evipan and omnopon anaesthesia. During the next fortnight her haemoglobin fell from 30% to 18%; her condition was then very bad and vomiting was frequent. A second blood transfusion, similar to the first, though the blood was a few days older, was then given. There was no rigor and she had a good night. Next evening the nursing staff, who had found her a most quiet and reasonable patient, without any sign of mental derangement, noted "strangeness in her manner." She was in a confused and restless state for the next three days, talking nonsense, trying to get out of bed and, at one time, remaining in a sitting posture, with arms katatonically extended before her, for half an hour. Her temperature at this time lay between 99° and 100°. She became mentally normal again within a week of this second transfusion and remained so till a third transfusion of three pints of citrated blood was given a fortnight later. A sharp rigor followed this transfusion, and she showed slight jaundice later, but had a good night. Next day she was again insane, and continued in a noisy delusional state (alleging, for instance, that she had swallowed several sets of dentures) for four days, after which she became and remained mentally normal till her death one month later. Necropsy revealed no cerebral abnormality. An organizing fibrinous general peritonitis was present, the fibrin being particularly thick on the under surface of the diaphragm. The pelvic contents were bound into a solid mass of inflammatory and carcinomatous tissue. No metastases more distant than the glands at the aortic bifurcation were found. There was unilateral hydronephrosis due to a nodule of growth in the right ureter. The blood urea post mortem was 69 mg. per 100 c.cm.

The most likely explanation of the two sudden and temporary attacks of madness, following blood transfusions, appears to be in terms of delirium due to low-grade peritonitis. But the precipitating effect of the transfusions in a patient at all other times mentally normal was regarded as a (perhaps) previously unrecorded phenomenon.

GOFFREY ROBINSON, M.B., B.Ch.,
Pathologist, Department Royal Hospital, Brompton

Reviews

HOSPITAL DEFICITS

The Hospitals Year-Book, 1941. Central Bureau of Hospital Information, 12, Grosvenor Crescent, S.W.1.

Hospitals, so prompt in doing their work, seem to be extraordinarily tardy in reporting on it. Thus the *Hospitals Year-Book, 1941*, which appears in September of that year, embodies the statistics of hospitals only up to the end of 1939, and even for that year they are incomplete. Of the 750 voluntary hospitals in England and Wales outside London only just over 600 have sent in returns in the form requested by the Central Bureau of Hospital Information, and of the 124 hospitals in Scotland only 75 have done so. In a number of cases the difficulty is explained by the fact that, in spite of repeated appeals, the hospitals have neglected to base their accounts on the calendar year. However it arises it is a great pity, because it leaves the picture of the service and of the financial position of the voluntary hospitals unfinished. In London the hospital secretaries are more co-operative, and of the 158 voluntary hospitals all but five have made the necessary returns. These show that the number of new in-patients in 1939 was 240,622, and of new out-patients just upon 1,700,000. The financial position in London is not, on the face of it, very satisfactory. The total receipts, lumping together capital and maintenance accounts, amounted to £5,366,462, but the expenditure was more than half a million more. In the Provinces the receipts and expenditure more nearly balanced, and in Scotland there was a surplus of over a quarter of a million. If capital costs be disregarded, however, the position is much better, with a small surplus on maintenance in London, as against a deficit the year before, and quite handsomely increased surpluses in the rest of Great Britain. There is a remarkable steadiness in the way in which hospitals are supported by voluntary gifts; but expenditure increases at a greater rate than income, and the recurring deficiency in the working of some of the metropolitan hospitals is becoming a serious problem, the more so when the heavy war taxation is contemplated, a factor which hardly makes itself felt in the figures for 1939. Of the London teaching hospitals nine showed surpluses in the year under review, but two others—the Royal Free and Westminster—had deficits of £22,000 and £21,000 respectively; the Royal Northern had a deficit of £23,000, and Queen Mary's of £10,000; while in the Provinces the Queen Elizabeth Hospital, Birmingham, had a deficit of £34,575, and the Royal Berkshire Hospital, Reading, one of £10,400. All these deficits were on maintenance account. Rather more than half of the hospitals of London show deficits, just over one-third of the hospitals in the Provinces, and one-fifth of the hospitals in Scotland.

Lord Plender, who writes the financial review this year in place of Sir Charles Harris, says that a partial remedy for this serious state of affairs may be found in regional controlling organizations, which in his view not only should be advisory but should have power in cases of proved need to exercise a measure of control over expenditure. He adds that this method might not be acceptable to many hospitals, in which case the local authorities should be requested to assist out of the rates. Even such measures might not prove adequate in the existing and post-war situation, and it may become necessary for the State to make grants in aid, as is clearly foreshadowed in the recent statement by the Minister of Health on Government post-war hospital policy. Lord Plender believes that the system of regional councils and a central council, now being promoted by the Nuffield Provincial Hospitals Trust on the recommendation of the

Sankey report, will help to solve the difficulties, and this is a view held in many responsible quarters.

The *Year-Book*, which contains the usual directory, is as useful as ever and more exciting than before, for it includes vivid illustrated accounts of the bombing of St. Thomas's Hospital and the Coventry and Warwickshire Hospital. Lord Horler contributes a short article on shelter hygiene, and Sir Alfred Webb-Johnson, P.R.C.S., one on the role of auxiliary hospitals and convalescent homes in wartime.

PRICE'S MEDICINE

A Textbook of the Practice of Medicine. By Various Authors Edited by Frederick W. Price, M.D., F.R.C.P. Sixth edition. Oxford Medical Publications. (Pp. 2,032. 35s. net.) London: Oxford University Press. 1941.

It is a great achievement, for which editor, contributors, and publishers must be congratulated, that *A Textbook of the Practice of Medicine*, by various authors and edited by Dr. F. W. Price, should have appeared in its sixth edition despite the trials and tempests of the past two years. Four new contributors have joined the team and three of the original writers of sections have died since the last edition. Much fresh matter has been introduced, and there are evidences of much rewriting of sections. A valuable innovation concerns a standard plan for the names of drugs (in which Mr. H. Davis, Ph.D., has collaborated). English names (B.P. 1932 or one of the Addenda, or the B.P.C.) have been used throughout, and on the first occasion on which the official name is mentioned in a section on the treatment of any particular disease this is followed by the name in the *U.S. Pharmacopoeia*, and then, in brackets, the names of the most widely known proprietary preparations of corresponding composition. There are twelve new illustrations, all concerned with electrocardiography, but the general size of the book remains the same. Monographs appearing for the first time include such subjects as pink disease, rupture of the intervertebral disk, and the heart in hypothyroidism. The haemorrhagic diseases have been reclassified, and there are other rearrangements and some new features in nomenclature. Altogether this is a worthy product of the London school of medicine—a most valuable textbook, and fully deserving of a wide sale.

UROLOGY

Office Urology. With a Section on Cystoscopy. By P. S. Pelouze, M.D., Assistant Professor of Urology, University of Pennsylvania. (Pp. 765; 424 figures; 1 plate. 50s. net.) Philadelphia and London: W. B. Saunders Company. 1940.

This is an excellent book on diagnostic and medical urology, especially suited to senior students, general practitioners, and such urologists as are too prone to think almost exclusively in terms of surgery. The illustrations and print are admirable, but the book is rather heavy to handle.

Professor Pelouze's pages are packed with sanity, humour, and tolerance for misplaced enthusiasm. Gentleness is persistently praised: "It is better to be a physician who does not cause shreds than one who tries to clear them up." Healthy scepticism is shown in saying that "the idea that one can tell safely from the size and shape of a shred just what part of the canal it came from is much like the old dream that one could tell from the microscopic study of urinary cells exactly in which section of mucous membrane they originated." Most diagnoses of necrospemia, we are told, are erroneous, and neglect the fact that "individuals who have not had an emission of semen for two weeks or longer commonly show no sperm motility." Among minor errors one may note "Pezzar" instead of *de Pezzar* (pp. 17 and 424), "Harry" instead of Hurry Fenwick (p. 155), "Thomas Walker" for Thomson-Walker (p. 175), and "diverticuli" for diverticula (p. 386). In Fig. 324 surely the prostatic lobe shown is the left, not the right.

The author is rather fond of "obtunded" for blunted. In Fig. 85, showing a smear from "non-gonococcal urethritis," we are told that the Gram-negative diplococci present (many of which are intracellular) are much larger than gonococci; but with such suspicious appearances one would presumably not exclude gonorrhoea merely by slight variation in size. One may not agree with the statements that the upper pole of the epididymis is the one most commonly affected by tuberculosis; that vesical papilloma rarely causes bleeding until the villi are long enough to be caught in the bladder sphincter; that in intravenous urography a compressing abdominal air cushion should be used; or that there are bladder stones too dense to be crushed.

Prostatectomists should remember that factors in increased frequency of micturition in the elderly may be loss of bladder elasticity, flabbiness of abdominal muscles, diminution of renal ability to concentrate urine, and also prostatophobia. Of rejuvenation methods the author says: "Drawing the line between what is true sex invigoration and what is psychologic sex stimulation in one who simply feels better is beyond the possibility of science." The part played by imagination in urethroscopy, and the ability of the instrument to produce many of the appearances seen, are emphasized. Finally, the reader is wisely advised not "to think of patients solely as urogenital systems around which God has draped a few other functioning structures." But it is impossible briefly to do justice to this challenging volume, which contains valuable chapters on the psychic factors of urogenital symptoms, on the sexual problem, and on cystoscopy and roentgenography, and which should be read by all interested in urology.

Notes on Books

A monograph by Dr. TORFINN DENSTAD on the Importance of Radiological Investigation in Cardiology, with Special Reference to the Significance of Cardiac Enlargement, is published as a supplement (No. XL) to *Acta Radiologica* (Stockholm, Sw. cr. 8). In this the author stresses the value of radiology in estimating the degree of cardiac enlargement in heart failure and, hence, as an aid to prognosis. Radiological investigation is of special importance in cases in which progressive cardiac enlargement is not accompanied by a corresponding deterioration in the clinical picture. In general, the author regards radiology as of more significance than electrocardiography, with the obvious exception of infarction. In hypertension, he says, the size of the heart and the symptoms are of more prognostic importance than the height of the blood pressure. Mitral defects, acute rheumatic carditis, chronic pericarditis, aortic aneurysm, thyrotoxicosis, and auricular fibrillation are among the other conditions which are dealt with from the radiological aspect.

Sokol: The Czechoslovak National Gymnastic Organization, by F. A. TOUFAR, is published at 6d. by George Allen and Unwin. The wonderful Sokol movement was founded and grew during the years of national rebirth and development and became closely associated with modern Czechoslovak culture. Though a non-political organization, it had, because of its democratic and progressive activities, come to play an important part in the political life of the nation. It was a national movement which included men, women, and children, and its object was to harden them physically and to train them in self-control, voluntary discipline, and moral firmness. Largely due to Sokol, its splendid organization, its ideology, and its results, the Czechoslovak nation became known abroad under its own name. This booklet gives a concise and clear statement of the whole movement. The immensely improved standard of physical fitness in our Forces which has followed the introduction of physical training shows the potential benefits we could gain by a nation-wide adoption of Sokol. It stands for individual, local, and national happiness.

Preparations and Appliances

TWO-MINUTE SUPRAPUBIC CYSTOTOMY

Dr. GRAHAM HUMBY writes from the Hospital for Sick Children, Great Ormond Street:

The classic operation for suprapubic cystotomy seems rather elaborate for such a common procedure, and so a simple "grab" bougie has been designed to complete the operation in two minutes.

The bougie is passed into the bladder and pressed against the abdominal wall just above the pubis—there is no need to fill the bladder with water; the jaws are then opened and the tissues overlying the gap in the jaws are incised (1 1/2-in. incision). This allows the jaws to protrude through the abdominal wall; the de Pezzer is then clamped by the jaws and pulled back into the bladder; the jaws are loosened and the bougie withdrawn from the urethra. No stitches are necessary.

AN EASILY MADE VEIN-SEEKER

Captain W. NORMAN TAYLOR, M.B., B.S., D.A., R.A.M.C. writes:

In these days of prolonged intravenous work, drip transfusions, continuous hexobarbitone anaesthesia, and the like, the usefulness of a vein-seeker is becoming more and more apparent. One can easily be made from the following: (1) the barrel of a 1 c.cm. syringe, preferably all-glass to facilitate boiling; (2) a short length of soft rubber tubing of suitable size to fit over the syringe; and (3) a small serological test tube

about the same size as the syringe. The diagram shows the three parts fitted together, and with an intravenous needle attached.

Sterilization can be done by boiling or immersing the parts separately in an antiseptic solution, followed by a rinse in sterile saline. For use the apparatus is filled with sterile normal saline or citrate solution. The simplest method is to draw the saline from a rubber-capped bottle—for example, an old "novutox" bottle—which is held upside down, so that the needle of the vein-seeker points upwards. In this way air bubbles will not get into the apparatus.

When full of saline or citrate the central rubber portion of the apparatus is squeezed and the needle inserted under the skin over the vein. Then on releasing the rubber a negative pressure is created. The needle is then inserted into the vein; the blood automatically flowing back into the syringe. The needle should be pushed along the lumen of the vein for a short way to make sure it is well in. (This type of vein-seeker can be firmly fixed by strapping over the syringe and over the serological tube.) The injection or transfusion is then made into the rubber portion, which thus forms an artificial vein readily accessible. A fresh piece of rubber tubing should be used for each operation, otherwise it may leak through previous puncture holes.

THE SPRUE SYNDROME

Many diseases (amoebiasis and undulant fever, for example) formerly thought to be confined to the Tropics are now found in Northern countries, and it seems probable that sprue, which for over half a century has been regarded as a typical product of the Tropics, may also have a much wider distribution. In its geographical range tropical sprue is mainly found in the Far East—India, China, Malaya, Ceylon—and to a lesser extent in South America and the southern States of the U.S.A., but is rare in Central Africa. Europeans, especially those long resident, are particularly liable to attack, without predilection for sex. Sprue begins mostly in the middle decades of life, small children being free from the disease. It is characterized by glossitis, stomatitis, steatorrhoea, meteorism, emaciation, and a steadily progressing anaemia of the pernicious type. Biochemical studies point to a general breakdown of digestion and assimilation; there is therefore failure to absorb fats, sugar, and calcium, while the hydrochloric acid and pepsin of the gastric juice are diminished and often, as in pernicious anaemia, absent altogether, and the intrinsic factor is missing (Castle and Townsend). There are two facts about sprue which especially confuse the issue of its aetiology. The first is its remarkable latency, for it may declare itself in a former denizen of an endemic area twenty-five years or even longer after return to a temperate zone; the second is its liability to relapse after many years of freedom from symptoms.

During the last fifty years theories as numerous as the remedies advocated have been advanced as to the origin of sprue, implicating diet, worms (*Strongyloides stercoralis*), yeast infection (*Monilia psilosis*), "dry rot" in houses (a very popular theory in Ceylon), and the faeces of termite ants (Jepson). As to the pathology of the disease, many of the changes in the epithelium of the small intestine formerly considered specific are ascribed to agonal and post-mortem changes so liable to occur in tropical countries. No readily ascertainable pathological changes* are demonstrable in the intestinal tract, but on microscopical examination there is usually evidence of chronic inflammation. The

essential lesion appears to reside in the ileum, which is generally much distended with gas, the walls being atrophic and diaphanous. The absence of a distinctive pathological picture brings sprue into line with idiopathic steatorrhoea, pernicious anaemia, and pellagra, with which it has many clinical features in common. But the sprue syndrome can be mimicked by other dissimilar processes involving the ileum and interfering with its normal functions: such are mesenteric tuberculosis, lymphadenoma, ulceration, malignant disease, gastro-jejuno-colic fistula, or a badly functioning gastro-jejuno-stomy. In fact, whenever a state of "chronic jejuno-ileal insufficiency" is brought about the clinical and biochemical features of tropical sprue are reproduced (Bennett and Hardwick¹). This applies not only to tropical sprue but to coeliac disease in children and idiopathic steatorrhoea in adults. Since 1932 the possibility of a disease identical with tropical sprue but distinct from idiopathic steatorrhoea (with bone changes and deficiency of vitamins D and K) has been discussed by Hess Thaysen² in Denmark and in Northern Europe. He claimed that non-tropical and tropical sprue were identical as they had the same pathology and were amenable to the same lines of treatment. This conception is not hard to entertain if it is accepted that the sprue syndrome results from damage to the villi of the small intestine, and this has been confirmed by Markoff,³ who has reported the superposition of sprue in a patient in Switzerland from whom 1.5 metres of the ileum had been removed surgically.

Pellagra presents a medical conundrum which may be taken as an analogue of sprue. As is well known, this is a comparatively common disease of tropical and subtropical countries in rural inhabitants subsisting upon an unbalanced dietary deficient in protein, and it is curable by nicotinic acid. In many features pellagra resembles sprue in the association of glossitis and stomatitis, frequent diarrhoea with occasional steatorrhoea, achlorhydria, and sometimes with anaemia of the pernicious type. In its geographical distribution pellagra frequently overlaps sprue. Thus Wood⁴ showed that pellagra and sprue are closely associated in the southern States of the U.S.A., and other observers (Manning⁵) have described a mixture of sprue and pellagra in the West Indies as *Psilosis pigmentosa*, while it is certain now that the pellagra syndrome (with characteristic dermatitis) may be grafted upon sprue as also upon coeliac disease and idiopathic steatorrhoea.⁶ In pellagra mouth symptoms may long precede the fully developed disease, and these cases have been termed "larval pellagra" or "prepellagra." In a substantial number the fully developed picture of pellagra may never ensue, though equally amenable to nicotinic acid

already reported.⁴ In a further paper,⁵ however, on six patients with polycythaemia rubra vera, it is shown that the haemoglobin content and the red and white blood cell counts are brought nearly to normal levels after amounts of P^{32} varying from 12 to 50 mc. Very marked clinical and symptomatic improvement accompanied the haematological changes, and periods of remission up to a year are recorded. The retention of P^{32} in the red blood corpuscles is the same in the polycythaemic patients as in normal individuals, and it is its concentration in the bone marrow which produces the favourable clinical results. The increased amount of spongy bone in the patients would account for the finding that the quantity of P^{32} excreted by them in the urine and faeces is much less than in normal individuals; here the report⁶ of a case of polycythaemia in which marked thickening of the skull occurred over a period of six years is of interest. Since radiophosphorus has never produced nausea, vomiting, or any clinical ill effects after its administration, this form of therapy would seem to be the most acceptable for polycythaemic patients at the present time.

BOVINE TUBERCULOSIS IN AUSTRALIA

With the object of ascertaining the present frequency of tuberculosis of bovine origin in Australia, R. Webster¹ has typed tubercle bacilli cultivated from 370 miscellaneous specimens sent to the Commonwealth Health Laboratories in Melbourne for diagnosis. Although pulmonary tuberculosis may occasionally be due to the bovine type of tubercle bacillus, sputum was excluded from this investigation in order to concentrate it on those forms of the disease which are known to be more often of bovine origin. Among the 306 patients from whom the cultures were obtained 183 were adults, and in all of them, whatever the site of infection, the organism was of human type. Among 123 children there were only 11 with infections due to the bovine type: in one of these patients it was recovered from both a bronchial and a mesenteric gland; the remaining 10 were all examples of cervical adenitis. Tuberculous meningitis, of which there were 57 cases in children and 8 in adults, was invariably due to bacilli of the human type, as were tuberculosis of the urinary tract (17 cases in children and 117 in adults) and bone-and-joint tuberculosis (20 cases in children and 45 in adults). It is apparently a general belief in Australia, derived no doubt from the data of A. S. Griffith and others obtained in England and Scotland, that tuberculosis of bones and joints, especially in children, is not uncommonly due to the bovine type of bacillus. This is evidently untrue of Australia at the present day; indeed, in this large series there is not a single example of any form of tuberculosis other than glandular in which a bovine bacillus was found. Not only is bovine infection restricted to this form, but its frequency among all cases of tuberculosis in childhood has fallen from 25.9%—as determined by a similar survey made by Webster in 1932—to 8.9% in the present series. The reason for this happy state of affairs is not far to seek. In 1930-1 some 3,000 cattle in ninety herds supplying the Melbourne area were tuberculin-tested, and 7.4% reacted. Since then the number of cows so tested has steadily increased, and in 1939-40 the number was over 28,000 in 727 herds; among these the percentage of reactors was only 2.8. During the same time pasteurization has become more common and more efficient. Webster concludes that tuberculosis of bovine origin is susceptible of total eradication; if progress on recent lines is maintained in the State of Victoria, to which these data mainly

relate, this end should be achieved. There are unfortunately no reasons for supposing that any such rapid progress is being made in this country, but the time has perhaps come when a further survey on similar lines to Webster's is needed to reveal the true position. Our data of type distribution are largely those compiled by A. S. Griffith anything up to twenty years or more ago, and it would be interesting to know whether the proportion of bovine infections in different sites and at different ages is still about the same, or whether perhaps the frequency of bovine infection in meningitis and in tuberculosis in bones and joints is diminishing. Methods of cultivating tubercle bacilli have now been so vastly improved that their isolation, and differentiation by cultural characters when this is possible, are within the powers of many laboratories, and there seems to be no reason, except the present shortage of eggs for making the necessary media, why cultivation should not become a routine procedure.

ACUTE LARYNGITIS AND H. INFLUENZAE

So much has the influenza bacillus been overshadowed by viruses in the aetiology of epidemic influenza that it is sometimes forgotten that *Haemophilus influenzae*, or at least certain of its strains, really are pathogenic to man. Most of the strains of *H. influenzae* isolated from the nasopharynx possess no capsule, but in 1931 Pittman¹ was able to show that certain strains do have a capsule containing a soluble substance which reacts with the homologous immune serum. On the basis of this reaction six serological types of *H. influenzae* (A to F) have been described. Of the organisms recovered in cases of influenzal meningitis 92 to 95% are said to have been of Type B. Recovery of an organism of this type from sources other than the meninges has been somewhat unusual. Sinclair,² however, now describes the isolation of Type B organisms from a series of cases of acute laryngitis associated with bacteraemia. Altogether there were ten instances in which *H. influenzae* Type B was isolated in cultures of the blood taken from patients desperately ill with acute laryngitis. Special interest attaches to the fact that eight of the cases occurred within a period of fifteen months from January 1, 1940, whereas the other two cases were the only ones observed during the seven preceding years. In three of the cases *H. influenzae* Type B was also isolated from the nose or throat, while in six other patients influenza bacilli were isolated from the nose, but no attempt was made to type the organisms. Incidentally, Alexander and his colleagues³ have now introduced a method by which these organisms can be identified from the nasopharyngeal mucus within thirty minutes. Acute influenzal laryngitis in children is a very serious disease characterized by a history of severe sore throat, laryngitis, fever up to 104° F., and a leucocytosis in one case up to 44,300 cells per c.mm., the polymorphonuclear leucocytes being greatly increased. Three patients died within eighteen hours of the onset of severe symptoms and a fourth within forty-eight hours. The six cases that recovered all received sulphanilamide, sulphapyridine, or sulphathiazole, but the number was too small for any conclusion to be drawn regarding the relative efficacy of these compounds. The patients who recovered showed little change for forty-eight hours except for the relief of respiratory distress: then improvement was rapid and recovery complete within a week. No influenzal virus could be isolated from these patients. It would seem that this form of laryngitis has in the past been comparatively rare, though the same syndrome, associated with a bacteri-

aemia due to *H. influenzae*, was described in France in 1936 by Le Meirre, Meyer, and Laplane.⁴ Now that attention has been drawn to it acute influenzal laryngitis may prove to be more common than was supposed.

HEPARIN IN CAVERNOUS SINUS THROMBOSIS

Cases of thrombosis of the cavernous sinus may be divided into two groups—a posterior otogenic group in which the thrombosis extends into the cavernous sinus from the petrosal sinuses, infection thus reaching its posterior end; and an anterior group in which the primary focus is situated in the accessory sinuses, the eye, or the skin of the face, the infection reaching the cavernous sinus at its anterior extremity. In the first group the infection is almost invariably streptococcal; in the second it may be streptococcal, but if it arises in a furuncle on the nose or lip it is likely to be caused by the *Staphylococcus aureus*. Although there are reports of a few recoveries, in which it may be assumed that the clot in the cavernous sinus itself remained aseptic, in general the prognosis is almost hopeless. Surgical treatment has proved of little avail, whether the cavernous sinus be approached from behind by the temporal route for reaching the Gasserian ganglion in the aural cases, or by the orbit in the anterior group.⁵ Eagleton⁶ planned to put the cavernous sinus at rest by ligation of the internal carotid, but he soon abandoned this as no good came of it, and until the introduction of the sulphonamide drugs no further progress was made. The posterior otogenic type, which sometimes progresses with fulminating rapidity, is rare. It is in the less uncommon anterior type originating in a staphylococcal infection of the skin that two helpful observations have now been reported by Champ Lyons.⁷ It is necessary not only to control the blood infection by chemotherapy, for which sulphathiazole is required as these infections are staphylococcal, but also to prevent extension of the thrombosis, for which purpose heparin is now available. By using these two remedies Hoople and Blaisdell⁸ have been able to report a case of recovery in a woman of 22, a previous case in a boy of 14 treated only by sulphathiazole having ended fatally in nine days. Le Roy Schall⁹ also records details of three staphylococcal cases (of which two were those in the care of Champ Lyons) which recovered on this plan of treatment.

Bacteriological examination is essential in order that the appropriate drug may be used with certainty, and the heparin is administered by a continuous intravenous saline drip. To each 100 c.c.m. of saline solution 1,000 units of heparin—i.e., 10 mg.—is added. This solution is allowed to run into the vein at such a rate that the clotting time of the blood is maintained at about ninety minutes. Should it be necessary to resort to some surgical intervention to evacuate an abscess, the heparin would have to be stopped. The coagulation time of the blood returns to normal in about four hours, so that the indications for stopping or continuing the administration of heparin in relation to operation are fairly evident. In one of the reported cases the heparin was administered for seventeen days, and in another for nine days. The total dosage may amount to 225,000 units. The heparin cannot be expected to exercise any influence upon a clot already formed, but it appears to be capable of preventing any further extension, and the results are certainly encouraging in the commoner type of cavernous sinus thrombosis.

BRADYCARDIA IN JUVENILE RHEUMATISM

It is commonly accepted that tachycardia is the usual indication of cardiac involvement in juvenile rheumatism, but according to A. J. Glazebrook and S. Thomson¹ slowing of the pulse rate is a common feature of the first attack of rheumatic infection in adolescents and young men. They record observations on the pulse rate in a hundred consecutive cases of acute rheumatism in boys and youths aged from 15 to 20 years. These cases fall into three groups. In one the pulse rate was commensurate with the temperature—that is, an increase of 10 beats a minute for every degree Fahrenheit. In the second group there was some increase in the pulse rate but not to a degree commensurate with the rise in temperature, and in the third there was no quickening but a slowing of the pulse rate, which fell below the normal rate for the individual irrespective of any pyrexia. There were thirty-eight cases in the first group, thirty-two in the second, and thirty in the third. Histories showed that bradycardia was more common in those suffering from their first attack of rheumatism, and of the thirty cases in the third group the bradycardia occurred early in the illness, usually within the first four days. (The cases were observed in a large institution, and it is probable that the records of the pulse rate were kept at an earlier stage of the disease than would happen in ordinary hospital practice.) In some cases the slowing of the pulse was transient, lasting only two days in one instance. Treatment did not appear to affect the appearance of bradycardia. Salicylates in moderate and in massive doses, antistreptococcal serum, and special immune serum were among the methods used; bradycardia occurred in patients treated by any one of these methods and was also seen in control cases given no specific treatment. Saturation with vitamin C and with vitamin B was also employed in some cases, but there was still bradycardia. A slow pulse was found in every degree of severity of the disease, but in the early stages of rheumatic infection such slowing seemed to be of serious prognostic significance as regards permanent cardiac damage. Half of the patients with bradycardia developed permanent damage of the heart compared with 30% of the rest of the patients observed. Electrocardiography gave evidence of heart-block in three patients only. In the majority of the group examined there was a simple sinus bradycardia, with some prolongation of the P-R interval. An exaggerated degree of sinus arrhythmia was often found. It is held that these findings suggest the existence of vagal over-stimulation, brought about by the action of the rheumatic toxins on vagal nerve terminations. Hence Glazebrook and Thomson have come to regard slowing of the pulse in juvenile rheumatism as an index of the severity of the toxæmia, believing that it is essentially due to the action of streptococcal endotoxins.

The King has approved the award of a Royal Medal of the Royal Society to Prof. E. L. Kennaway, M.D., F.R.S., director of the Chester Beatty Research Institute of the Royal Cancer Hospital, for investigations on the production of cancer by synthetic substances. The President and Council of the Royal Society have awarded the Copley Medal to Sir Thomas Lewis, M.D., F.R.S., for his experimental researches on the heart and the circulation and their disorders; and the Davy Medal to Dr. H. D. Dakin, F.R.S., for his pioneer work in biochemical research, and especially for fundamental contributions to the study of intermediate metabolism.

NETWORK PLAN FOR DEALING WITH INVASION CASUALTIES

BY

GORDON WARD, M.D.

This simple plan depends upon a few facts which can hardly be disputed. First, we cannot know until air and sea invasion starts what parts of the country will be most severely engaged with the enemy. Secondly, in most of these parts collection of the wounded by means of ambulances will be impossible for a period which high authority estimates as from one to seven days. Thirdly, even if the collection of wounded is possible it may often be undesirable because the nearest hospital is threatened or already destroyed. Fourthly, in these isolated areas, cut off from other means of medical assistance, casualties will have to be retained and treated near to where they occur, and with such facilities as may be there available.

These new facts almost compel the adoption of a scheme by which the country shall be covered with a network of aid-posts, which should be approximately one mile apart. In many moorland and forest areas the mesh will obviously be wider. In towns it may be considerably closer because town communications are so easy to obstruct. The exact size of the mesh does not matter at the moment. It will vary. But the one-mile mesh is chosen as ideal because the wounded will have to be carried in on stretchers, and even half a mile is a very long way to carry a heavy man or woman.

Those whom the Plan will Benefit

Before considering the nature of this network plan let us say something about the people for whose benefit it is designed. It is clear enough that local residents will benefit from the posts near to them. But they are not the only ones to be thought of. Everyone knows that our coast towns are nearly empty, and that they have not enough inhabitants to deal with hundreds of fires in empty houses. If the enemy sees fit, these towns will burn, and the remaining inhabitants will spread out into adjacent countryside. What else can they do? The network plan will ensure that these people are not left without medical help. Then again, there are thousands of troops who will be carried towards the enemy in motor vehicles. They cannot escape air attack and wounding. What is to happen to these casualties? Shall the tank stop to look for a doctor? The plainly marked posts of the network plan will go far to solve this difficulty. We dare not leave our wounded to die by the roadside or to lie forgotten in a cottage while it is in our power to arrange something better.

Composition of the Network

Now we can turn to the composition of the network. Much of it is already in place, some of it recognized, some still unrealized. In the towns there are hospitals, aid-posts with large trained staffs, and many excellent first-aid units connected with factories and works, railways, and so forth. It remains only to see that each has its place and is plainly indicated to the passer-by by a uniform sign. Then we must add any more that seem necessary. It must always be remembered that street fighting and the destruction of the larger aid-posts may wreck the town organization if reliance is placed on too few centres for medical aid. In the country things are not so good. There are only a few aid-posts and a very few up-graded first-aid points which could keep casualties for seven days. To these we should add certain units whose usefulness is often overlooked. In time of invasion the empty wards and idle staff of isolation hospitals must not be wasted. All asylums can deal with wounded, and most public assistance institutions and many sick-bays used for evacuees: these must all be roped in. There are also thousands of military aid-posts which will be available. All of these must be carefully entered upon a map in every county or rural district. Then the Home Guard casualty collecting posts, those of them which can keep casualties for seven days, must be added. Only then will it be possible to see what new posts must be provided to make the

network complete. I think the best people to set up these posts may be the members of those local invasion committees which are making such a success of all-in co-operation in East Anglia.

Supplementary Posts

Now as to the nature of these posts—that is, of the additional posts still required to make the network complete. They must be able to retain the wounded up to seven days; that is essential. They won't be able to provide major surgery or anything like that, at least in most cases. Very few will have a resident doctor. Even if all services combined, which they are not doing at present, it would not be possible to provide a doctor at every post, but by careful organization beforehand it should be possible to arrange that every five or six posts will come under the care of one doctor, who will attend where and when he is needed. He will probably have to walk and visit at night, but night visits are nothing new. In every post it should be easy to provide someone with first-aid and nursing experience. It will also be possible to provide those extremely important things—rest, warmth, and food, dressings, and morphine. These are not little things; they are far more important to the wounded than the services of a surgeon. In any case, if we do not provide them many of our wounded will have nothing at all except such things as may be found in a house chosen at hazard and utterly unprepared. We must have either ambulances or the network plan, and if the ambulances are not possible, as will happen in isolated cases, we must have the network completed as soon as possible.

Policy of Dispersal

Lastly, let us discuss one or two objections which have been raised. The first of these is the suggestion that this plan is something which a self-important individual (myself) has set up to compete with the A.R.P. services. Surely only wilful prejudice or insufficient knowledge of the network plan could prompt this view. The plan is a normal and logical extension of the A.R.P. services. The second objection sounds at first more plausible. It is that the network plan will dissipate both staff and medical supplies urgently needed at town centres. The obvious answer is that if invasion is going to dissipate and disperse casualties, and keep them dispersed, then we must disperse whatever is needed to deal with them. In isolated areas the policy of dispersal will be fully justified. In other areas both stores and personnel can be recalled if needed; but since our hospitals all carry upwards of one whole year's supply of dressings in reserve, the policy of the network plan does not really threaten them very seriously. And there is another point. These big hospital stores are all in places which are exceedingly vulnerable. The Nazi airmen cannot destroy every house in the country, but they could very easily destroy these big stores in the towns. Food and ammunition are dispersed; it is high time that medical stores were also dispersed, even if only for safety.

One last point: Army and civilian morale depend very largely upon the belief that casualties will be dealt with wherever they occur. At the moment this belief is a delusion. It is helping Hitler if we leave the wounded to die by the roadside, or throw them into the nearest house to be attended by anyone who chances to be there. That is what will happen if we do not take steps in time. It is quite easy to do better, and we ought to do it. I sincerely believe that the network plan is an anti-invasion measure of the very greatest importance for the maintenance of morale as well as for the assistance of soldiers and civilians.

F. A. H. Simmonds (*Tubercle*, 1941, 22, 183), who records his observations on 250 cases, states that effusions in artificial pneumothorax are less common if the lung is adequately freed by sections of adhesions. When effusions occur they are most common within three months of the operation. When valvular pneumothorax occurs the valve is in the bronchus connected with the cavity, where a more or less localized caseous bronchitis is present. Effusion is commonly preceded by signs of spontaneous pneumothorax.

SHAMMING NIGHT-BLINDNESS

BY

N. BISHOP HARMAN, M.B., F.R.C.S.

Eye tests are of two orders: objective and subjective. We can examine the eye in all its parts with our ophthalmoscopes and other instruments and watch certain reactions to light which are uncontrollable by the mind of the subject. But what the detailed vision of that eye may be we cannot find out except by the voluntary response of the subject. There are occasions when the objective findings and the subjective responses seem to clash. The eyes of a subject on examination may appear quite good in every detail, yet the visual response may be poor. The possibility of checking the visual response by special tests is a problem of interest and present-day importance; it is particularly so as regards seeing in a minimum of light—night vision.

The publication (*Journal*, September 6, p. 349) of the results of the examination of 700 subjects for night-vision reactions with the disk-spotting test has brought inquiries as to the possibility of using the test to distinguish between a real defect of night vision and a suspected shamming. To-day there are many branches of national service that require the citizen, whether a civilian or a member of the Services, to do work that entails ability to see in the dark. Inability to do so means not only danger to the subject but also danger to the community if that subject be truly night-blind or partly so. Is this inability always real or may it be sometimes false? How are we eye men to find out?

Shamming Bad Day Vision

Something of the same problem arose on occasions during the last war in the examination of men called up for military service. The eyes of a subject under detailed examination were found to be good, but the visual reaction was poor. Then I devised a test which enabled the examiner to check the visual reaction in some measure. This test has since been of much value in examining patients claiming workmen's compensation for eye injury whose visual reaction was much worse than the state of the eye seemed to warrant. The test is as follows:

Two Snellen's test types are fixed one on each surface of the same board. On one side the regular range from 6/60 to 6/6 is fitted. On the other side the types range from 6/36 to 6/5, but the arrangement of these slightly smaller types matches in pattern and in general appearance the normal set of types. The patient is shown No. 1 test type; say he reads three lines: V=6/24. Now No. 2 test type is exposed; if he again reads three lines his vision is really 6/18, and he is convicted of inconsistency and suspected of shamming deficiency. The test is easy to apply and has proved to be very useful.

Shamming Bad Night Vision

Checking suspected shamming of bad night vision is a much more difficult problem. If there is found in the eyes of the subject density or opacity of the media, or very small pupils that do not dilate, or defect of the fundus oculi, then the deficiency is likely to be genuine. High errors of refraction and the need for thick lenses will also make it genuine. But in some cases there is good daylight vision, no discernible sign of defect on the objective examination of the eyes, and no general defect of health or nourishment to explain the poor night vision reaction. There may be as complete an absence of any ocular evidence in confirmation of the night vision defect as there is of anomalies or lack of colour vision.

By applying the experience with the daylight test described above it is possible so to vary the use of the disk-spotting test as to make it a check upon the reaction of the subject. This can be done in two ways: (1) varying the light; (2) altering the size of the disks on the test.

1. *Varying the Light.*—The candle-box enclosing the standard candle has a projection tube through which the light passes to the white disks on the test board. A cap, like a pill-box lid, can be made with its flat surface of semi-transparent

grease-proof paper; the density of this film can be chosen so that it cuts off half the candle-light. Or the light may be increased instead of diminished: if a hand torch with a sliding or adjustable reflector be held alongside the candle-box the adjustment can be made so that the torch light reinforces the candle-light and increases it three or four times.

2. *Altered Disk Sizes.*—The size of the disks in the test board can be changed. The normal-pattern disks are 1/2 inch in diameter and 1/8 inch in separation from each other. In the test board (as made by Theodore Hamblin, Ltd.) there is space enough on the velvet surface of the base board between disk-groups 4 and 5 to allow to be pasted to it another set of disks, four in number, each of 3/4 inch in diameter, and separated by 1/4 inch. Thus the size and distinction of the disks in the candle-light can be suddenly altered by turning the test cover during the examination.

There are then three ways in which the test may be made more difficult or more easy. If the subject with bad night vision is genuine in his disability he will show this in his response to the variation of the test. When the light is less his vision will be worse; when the light is brighter he will see much better and at a greater distance. So also will he see somewhat better when he is shown the larger disks. For example, a subject whose response to the regular test was only 2.5 metres was tested this way. (The average response of normal subjects is at 5 metres.) After a full dark adaptation the varied tests were made. He could only count the disks in the reduced light at 1 metre; he could count them easily at 6 metres with the added light; he could count the larger disks in the usual fractional candle-light at 3.25 metres. There was thus reasonable consistency in the reactions of this subject to light variations, so the night-vision defect was considered to be real. In making these variations of the test in suspected cases it is desirable to have an assistant to help the examiner manipulate the test. The examiner should stand with the subject. Between each grade or alteration of the test the eyes of the subject should be covered, so that there will be no actual observation of the changing of the conditions of the test.

Conclusion

Applying tests to check subjective vision reactions requires much nous on the part of the examiner. It is a trial of wit against wit. The "cutest" one of the pair, examiner and examinee, will win the trial, but that is the normal reaction of a medical practitioner: he is always faced with problems in diagnosis and the interpretation of symptoms that demand acuteness of judgment.

THE YORK CLINIC AT GUY'S HOSPITAL

The building has recently been completed at Guy's Hospital of the York Clinic—the first psychiatric clinic to be erected in this country as part of a general teaching hospital. Its opening will have to be deferred until the end of the war, but its completion at this time is symbolic of a determination that when the conflict is over social and scientific progress will go forward hand in hand at an increased speed.

For fifty years Guy's Hospital has had a lecturer in psychological medicine, and more than 200 years ago its founder provided in his will for the care of forty chronically insane patients in a ward which stood in the hospital precincts. Later the Governors obtained the permission of the Charity Commissioners to transfer the funds available for this purpose to Bethlem Hospital. In accord with the developments of medical, and especially of psychiatric, science that have taken place since these old days the new clinic is intended to fulfil a very different purpose. "Functional" disorders, or psychoneuroses, have been found to result from disturbed minds, and the general need for early treatment of mental disorders has been stressed. The York Clinic has been constructed for the treatment both of psychoneuroses severe enough to require in-patient treatment and of psychoses. The purpose of having it within the precincts of a general hospital is twofold: first, to encourage the early treatment of all such conditions as can be admitted with no other formality than attends the admission of any other type

of case to a general hospital; secondly, to facilitate and intensify the teaching of psychological medicine in all its aspects, both as a social and as a medical science.

The building contains forty-two beds and has five floors, the ground floor being devoted to public rooms and offices, the basement to a laboratory, gymnasium, dining-room, etc., and the roof to recreation space. Those who planned the clinic have aimed to make it, within the limits available, a place where the patients can live without being confined to bed. For this reason there is the maximum amount of day space that it was possible to provide. The corridors are especially wide and can be used as lounges, and besides the public rooms already

mentioned there are occupation rooms on each floor. The majority of the accommodation is in single rooms, but there are some three-bed dormitories. The building is quiet and modern in appearance. The architects are Messrs. Thompson and Walford and Messrs. Stanley, Hall, Easton and Robertson, two firms with considerable experience of hospital requirements. The Board of Control also generously put the experience of its own architect at the disposal of the planners of the clinic.

Those who provided the money to build the clinic have allowed sufficient funds for a capital sum, with part of which it is hoped to provide some free beds; but for some time to come it will be necessary for the majority of patients to be charged fees which will meet a variety of needs.

For teaching purposes the clinic will work in close association with the out-patient department and with the existing half-dozen psychiatric beds provided by the Governors during the last decade. The increased contacts between the staff of other departments and the department for psychological medicine should have the desirable effect of bringing psychiatry still closer both to general medicine and to the other specialized branches.

MEDICAL WAR RELIEF FUND

THE FIRST YEAR'S WORK

The following report on the work of the Medical War Relief Fund during the first year of its existence has been approved for publication by the Committee of the Fund

In September, 1940, the Medical War Relief Fund was inaugurated to provide temporary assistance for British medical practitioners and their dependants who find themselves in financial straits as a direct result of war conditions. At the end of that month the first appeal for subscriptions was published in the medical press. The response, from both individual practitioners and medical organizations, has been most encouraging, and by the end of September, 1941, the contributions to the Fund had reached the total of approximately £34,000. To all who have subscribed so generously the Committee of the Fund wishes to express sincere thanks. It will not be considered invidious to refer in particular to the splendid help received from medical practitioners over-seas who have not forgotten the needs of their colleagues in the Home Country. A cable has recently been received from the British Medical Association in Australia intimating a donation of £4,500 (Australian) contributed by members in that country. This is additional to the total of £34,000 already received. The Malaya Branch of the B.M.A. has contributed more than £300, and a first contribution from the Canadian Medical Association, consisting entirely of subscriptions collected from doctors in British Columbia, amounts to nearly £350. Other generous donations have been received from organizations in Australia, Canada, Hong Kong, and Uganda, as well as from individual practitioners in various parts of the Empire.

Classification of Applicants

The first awards were made by the Distribution Subcommittee on November 13, 1940, and between this date and September 30, 1941, forty-four applicants received assistance, the approximate average being one a week. These forty-four cases do not readily lend themselves to any simple method of classification, for the financial difficulty which led to the application was frequently due to more than one cause. In five cases the beneficiaries are dependants of doctors killed on active service with the Forces, and an equal number of awards have been made in cases of doctors killed—or, in one case, disabled—by enemy action while engaged in civil defence duties or ordinary civil practice. The largest group, numbering sixteen, is made up of doctors whose difficulties were primarily attributable to the bombing of their homes or consulting rooms, with destruction of or damage to their cars, furniture, instruments, or other possessions. Assistance was given in seven cases to men who were temporarily in difficulty owing to loss of patients through evacuation, and in eight cases to medical officers and ex-officers who were in financial straits owing to reduction of income as a result of joining the Services, or required help in re-establishing themselves in their practices after relinquishing their commissions on the ground of ill-health. There remain three miscellaneous awards, one of which was made to the wife of a doctor who continued his work in one of the Channel Islands at the time of the German occupation and is therefore temporarily unable to support his family in England.

Form and Amount of Assistance

Some of the applicants responded to the invitation to state the amount of the gift or loan which they found it necessary to request; others preferred to leave the form and extent of the assistance needed to the judgment of the Distribution Subcommittee. When definite requests have been made the full sum asked for has not always been given. On the other hand, there have been cases in which the amount awarded has been in excess of the evidently too modest demand. The aim has been to provide, so far as possible, a real solution of the immediate problem and to remove the attendant anxiety by giving promptly such assistance as medical practitioners would wish to see rendered to their stricken professional colleagues. Care has been taken to avoid not only parsimony but also too lavish generosity; for the Subcommittee has been mindful of the future

B. G. Hoo (*Acta paediatr.*, 1941, 28, 293) records a fatal case of congenital malaria with congenital heart disease in a child. The mother had her first attack of malaria one day after the child's birth. Malarial plasmodia were found in the child's blood on the twentieth day of life. During the period when parasites were found in its blood the child had no fever and there was no enlargement of the spleen. Only later was there a slight rise of temperature.

and the probability that many more applications will be received before the war is over. As is stated above, only five applications have hitherto been received from dependants of doctors killed on service with the Forces, but as our armies become more actively engaged more casualties must be expected, with a consequent rise in the number of dependants left in difficult circumstances. It must also be assumed that as men are released from the Services many of them will need temporary financial help in the difficult task of resuming their practices. But apart from such cases as these, there can be little doubt that as the war goes on and economic difficulties become greater the number of applications for assistance will steadily increase.

Grants to widows and other dependants have inevitably taken the form of gifts, and in a considerable number of other cases this appeared to be the only appropriate method of help. Applicants whose financial problems seemed likely to be merely temporary requested and received loans, but in some of these cases it was thought desirable to give part of the sum required as a gift, particularly when it was essential to replace professional equipment and other possessions at a cost in excess of the amount of war damage compensation likely to be paid. Twenty-eight applicants have received gifts amounting to £3,420; seven have received loans totalling £1,690; and nine have received both gifts (£1,375) and loans (£1,350) amounting in the aggregate to £2,725. The total of the gifts is £4,795 and of the loans £3,040, the grand total up to September 30, 1941, being £7,835. One loan of £200 has already been repaid in full, and another is being repaid in regular monthly instalments.

Co-operation with Other Bodies

The Distribution Subcommittee has worked in the closest co-operation with the Royal Medical Benevolent Fund, which is strongly represented on the Subcommittee. In two ways the assistance of this organization has proved of particular value. First, there have been cases in which widows with young children have been voted considerable sums towards educational and other expenses over a period of years. In such cases the R.M.B.F. has been good enough to accept the responsibility of administering the awards, and has been given discretion to vary the instalments according to the needs of the families concerned from time to time. This fortunate arrangement ensures for these families the maintenance of a friendly interest in their welfare throughout the difficult years immediately ahead, and the continued availability of advice and assistance should such be required in the more distant future. Secondly, the experience of the R.M.B.F. has been of great assistance in obtaining supplementary grants from other organizations, and especially in securing pensions for widows whose need of regular help may well continue beyond the time when the Medical War Relief Fund will cease to exist. Of the forty-four applicants who received awards from the Fund, no fewer than eleven have been introduced with successful results to various benevolent societies, including the R.M.B.F. itself.

The Committee deeply appreciates the hospitality shown by the British Medical Association in providing accommodation for its meetings and those of the Subcommittee, and the assistance voluntarily given by the secretarial, accountancy, and clerical staff of the Association in connexion with various aspects of the work of the Fund. The Committee wishes to acknowledge also the help received from the secretary of the Subcommittee, Mr. E. C. Pennefather. His wide experience with the Royal Medical Benevolent Fund and his knowledge of other charitable institutions have been of great value. Thanks to the generous co-operation given by the B.M.A. and the R.M.B.F. the administrative expenses during the first year, including the cost of printing, stationery, application forms, etc., and the cost of postages in connexion with appeals and the acknowledgement of subscriptions, amount only to approximately £150—2% of the amount expended in awards and less than 0.5% of the total amount contributed.

The address of the Honorary Treasurer and the Honorary Secretary of the Fund is B.M.A. House, Tavistock Square, London, W.C.1. A statement explaining the constitution of the Fund and containing brief accounts of six typical cases was published in the *Journal* of April 12 last (p. 566). Additional cases are summarized below.

Illustrative Cases

Dr. G., a senior general practitioner, lost his life in a raid in which his house was completely destroyed. His only child was killed at the same time. The widow lost her clothing and other possessions, and although the doctor's estate would eventually furnish her with a modest income she was temporarily without means. She was awarded a suitable sum as a gift to provide for her immediate needs.

Dr. H., another general practitioner, had invested his savings in a small practice, which he purchased in the early part of 1940. A year later he was killed by enemy action. There was little left for the widow, who was also a casualty, but it seemed that she would be capable of earning her livelihood when she had recovered from her injuries. She was awarded a grant which she has gratefully described as a "magnificent gift." She has now found suitable employment.

Dr. I. is one of the many specialists whose incomes have been seriously affected by certain restrictions imposed by emergency legislation. In addition, Dr. I. has been "bombed out" repeatedly, and has had the misfortune to see the company in which his savings were invested become bankrupt as a result of war conditions. Despite economies, both domestic and educational, and a tendency to improvement in his greatly reduced practice, he found himself unable to meet a number of pressing debts. The amount required was provided by the Fund, one half of the sum being awarded as a gift and the other half as a loan. Dr. I. has expressed his profound gratitude and his intention to repay the loan as soon as possible. "With any reasonable luck," he writes, "I should now be able to hold out here until the war is over."

Dr. K. is an elderly consultant. His consulting rooms were bombed and completely destroyed with the furniture, instruments, and books which they contained. The income from his practice had diminished considerably owing to the war, and although he had no debts of any magnitude, neither had he the means to acquire new premises and equipment while awaiting the payment of war damage compensation. He was awarded a substantial sum for this purpose—the greater part as a loan and the remainder as a gift. He writes: "It just feels as if I had emerged from the black-out into brilliant sunshine. The feeling of relief is intense. Will you please express my great gratitude to the Committee for the chance of a fresh start." my great gratitude to the Committee for the chance of a fresh start.

Dr. L. was a comparatively young man who combined general practice with a part-time public health appointment. He had had little time or opportunity to save, and when he died of wounds on active service with the R.A.M.C. his indebtedness to an insurance company was greater than the amount that could be realized by the sale of his practice. Mrs. L., who has young children, will receive a small pension from the Army, and she hopes to place the children in boarding schools in order that she may be free to take up remunerative employment. To assist in the education of the children the Fund has awarded her a gift which will be administered over a period of years by the Royal Medical Benevolent Fund; and Mrs. L. has been introduced to another society, which has promised an additional grant for educational purposes.

Dr. M., a specialist serving in the R.A.M.C., was killed on active service, leaving a widow and child. Mrs. M. has been awarded a gift to be administered by the Royal Medical Benevolent Fund which will suitably supplement her small income during the child's remaining years at school. As Dr. M.'s elderly mother had been partially dependent on him a similar arrangement has been made in her case; and Mrs. M. senior has been introduced to two other benevolent societies, one of which has awarded her a small grant, while the other has given more permanent assistance in the form of a small pension.

The Federation of American Societies for Experimental Biology announces that in March, 1942, it will issue the first number of a quarterly publication to be named the *Federation Proceedings*. This will be published by an editorial board representing the five constituent societies of the Federation: the American Physiological Society, the American Society of Biological Chemists, the American Society for Pharmacology and Experimental Therapeutics, the American Society for Experimental Pathology, and the American Institute of Nutrition. Four numbers of the new periodical will appear each year. Abstracts of the papers will be grouped under the societies to which they are communicated and will be indexed according to subjects and authors. The subscription price to non-members is \$4.00 (\$4.50 foreign), payable in advance, on application to Dr. D. R. Hooker, managing editor, 19, West Chase Street, Baltimore, Maryland, U.S.A.

difference might have something to do with the different character of spread during the six-months period. All the wound cases in the ward had been fairly generously sprinkled with sulphanilamide powder.

Major H. W. RODGERS said that he had been working in a military hospital where an endeavour had been made to reduce the smell of wounds treated by the closed-plaster technique. They had encased the greater part of the plaster with some absorbent material soaked in antiseptic solution, and then had put another plaster on the top of that, so that there was a kind of chamber between the plasters. This reduced the smell considerably. Would it also reduce the risk of cross-infection?

Prof. PATERSON ROSS still thought that for the control of infection it would be a pity to introduce into the hospital another officer. The better thing would be a closer liaison between the bacteriologist and the surgeon.

THE OTO-LARYNGOLOGIST ON WAR SERVICE

At the meeting of the Section of Laryngology of the Royal Society of Medicine on November 7, the problems of the oto-laryngologist in the war were the subject of discussion.

Mr. E. D. D. DAVIS, president of the Section, who introduced the subject, said that on the outbreak of the war the work of the specialist, hospital and private, almost disappeared. In the E.M.S. each sector was left to make its own arrangements, and while some sectors rose to the occasion, in others the organization was half-hearted. He hoped that oto-laryngologists would insist upon sufficient staff, accommodation, and equipment within the framework of the E.M.S. to enable efficient service to be given to those who required it, and that in the R.A.M.C. oto-laryngology would soon be no longer the Cinderella of the specialties, without proper representation in the central councils. Only relatively few oto-laryngologists could be adequately employed in their own specialty in the Army, and the question was how to occupy such officers fully. But the successful practice of oto-laryngology required a sound knowledge of medicine, and particularly of surgery; the oto-laryngologist must not confine his attention to the ear, nose, and throat. Thus it followed that he could be trained within a short time as a war surgeon. He suggested that ear, nose, and throat work should be concentrated in one well-equipped unit in each E.M.S. sector, Naval base, Army command, and R.A.F. hospital, each unit to have a minimum staff of two surgeons and assistants.

The Royal Navy

The Royal Navy

Surgeon Rear-Admiral C. P. G. WAKELEY described the position in the Navy, where the ear, nose, and throat surgeon also served as a general surgeon. In many instances there would not be enough work for him to do if he were limited to his specialty. As a rule it was junior medical officers who were selected for ear, nose, and throat surgery. They were given practical courses and afterwards were sent usually to one of the large base hospitals to take over a department under a senior medical officer who was a surgical specialist and in his younger days had himself probably been an ear, nose, and throat surgeon. After experience at the base hospital for two or three years the young surgeon went to sea and probably became the specialist of the squadron to which he was posted, visiting acute cases in the ships of the squadron, and accompanying a case to the naval hospital or hospital ship and performing or assisting at operation. During all this time he was still doing general surgery. After several years, when he had attained the rank of surgeon commander, he might become a senior surgical specialist, with a younger officer under him as ear, nose, and throat surgeon, while he himself was responsible for general surgery. The Navy also employed civilian consultants, who were asked to see special cases at base hospitals and occasionally in hospital ships.

Specialism in the Army

Specialism in the Army
Major DOUGLAS GUTHRIE said that the military practice of the specialty inevitably differed considerably from the civil in its outlook upon prognosis and treatment. Radical operations

requiring long after-treatment had little place in the Service. The object was to return the man to his unit as fit and as quickly as possible. During the past two years in a clinic which numbered 3,000 new patients a year he had performed only one radical mastoid operation and not a single frontal sinus operation. Cases in the Army came under three categories: (1) routine cases, such as tonsillitis, deviated septum, and various forms of sinusitis; (2) chronic otitis, still extremely common in the Army and largely the result of long neglect; (3) headache persisting after correction of refractive errors and calling for attention from the ear, nose, and throat department. In Scotland there was good liaison between military and civil hospitals. The E.M.S. hospitals absorbed the overflow in busy times, and the convalescent hospitals took cases a day or two after operation, so that it was possible to admit and discharge cases and to operate three times a week, thus avoiding any waiting list, which in the Army would lead to hopeless muddle. He agreed that the ear, nose, and throat surgeon should be familiar with general surgery, particularly that he should be a potential traumatic surgeon, but not that he should be supposed to remove appendices or perform operations for hernia.

The Emergency Medical Service

Mr. V. E. NEGUS recounted some of the points in his paper published in the *Journal* of October 11 (p. 519). In his experience the oto-laryngologist in the E.M.S. was well and fully employed in dealing with injury and disease. In his section (IX) there were out-patient clinics for Service cases at six hospitals, civilian sick came from three hospitals in London, and in-patients were dealt with mainly at one large hospital where 200 out of a total of 2,000 beds were available for this special department. The volume of complaints such as acute and chronic otitis media, sinusitis, and tonsillitis, together with nasal and Eustachian-tube obstruction, required the services of a considerable number of specialists. Nearly half of all injuries of the head and neck affected parts other than the cranium, and in dealing with such cases the specialist with expert knowledge of the surgery of the ear, nose, and throat was indispensable. The role of the oto-laryngologist was to treat in his own ward-cases of disease within his province, and when casualties arrived to serve as an active member of the department dealing with injuries of the head and neck, in direct collaboration with the neurosurgeon, ophthalmologist, dental surgeon, plastic surgeon, and others.

The Royal Air Force

The Royal Air Force

Squadron-Leader DALZIEL DICKSON described the steps taken on the outbreak of war to establish ear, nose, and throat centres in the existing and projected R.A.F. hospitals. Almost all were staffed by specialists, most of whom had joined the medical branch of the R.A.F. They were in two categories: (1) those who had held specialist hospital appointments or had been in charge of departments in civil hospitals, and (2) those whose experience had been as assistants or house-surgeons. The former acted as regional specialists and the latter were allocated to aviation medical boards. All arrangements for the provision of officers in both groups came under the R.A.F. consultants department. The regional specialist supervised all researches in so far as they concerned his specialty, and he or his deputy visited each hospital and centre about every six weeks and was available for emergency work wherever required. Treatment was conservative, operation being resorted to only where this was specially indicated. The equipment of ear, nose, and throat departments had been standardized. Most of the departments were self-contained and had adequate bed accommodation and spare consulting and treatment rooms. Unusual cases were transferred to the larger hospitals. Cases of chronic suppurative otitis media which had found their way into the Service as a result of a superficial examination by the recruiting board accounted for a high proportion of such ear, nose, and throat morbidity as was found. Research problems formed a large part of the work of the consultant. He indicated some of these such as an investigation into the relative merits of means of ear protection during flight, the aetiology of air-sickness, and the standardization of hearing tests.

General Discussion

General Discussion

Major SCOTT STEVENSON said that otology in the R.A.F. was a career in itself, but in other Services this was not so. In the

Local News

SCOTLAND

Future Organization of Hospital Services

Mr. Thomas Johnston, M.P., Secretary of State for Scotland, together with Mr. W. R. Fraser, secretary of the Department of Health, recently attended a meeting in Edinburgh of the Scottish Branch of the British Hospitals Association to discuss post-war policy. Mr. Johnston pointed out that to overcome any local inadequacy of hospital accommodation it was first necessary to place on a more satisfactory footing the present loose partnership between local authority hospitals, voluntary hospitals, and the E.M.S. hospitals under State control. It was proposed, he said, as a first step to lay upon county councils and the councils of the larger burghs the duty of securing, in co-operation with voluntary agencies in the same field, that adequate hospital services were available, to all who needed them. To avoid wastage and to ensure the best use of resources, such services must be designed with a view to areas wider than those of individual local authorities, and the more highly specialist services would be afforded at teaching hospitals and other specially selected centres, while between the hospitals as a whole within the region there would be an appropriate division of functions. After discussion the co-operation of the British Hospitals Association was offered to the Secretary of State in any investigation of post-war problems that he may decide to undertake.

On the following day in Edinburgh an address was given by Lieut.-Colonel A. D. Stewart, superintendent of the Royal Infirmary, who also spoke of the need for a wider organization of hospital services. He declared that hospital organization had lagged far behind medical science and discovery. Voluntary hospitals had suffered from their individualism and isolation, and in many there was a financial crisis. They appeared, said Colonel Stewart, to be nearing the limit of their capacity. Either new sources of income must be found or expansion curtailed, in which case the initiative of hospital development would pass into other hands. Hospital waiting lists are a difficult problem in Scotland as elsewhere. Colonel Stewart explained that the more emergency work a hospital did the larger would be its waiting list. Edinburgh Royal Infirmary was carrying out emergency work, both surgical and medical, for Edinburgh and the whole south-eastern area of Scotland. In a progressive hospital waiting lists could never be completely overtaken, for advances in knowledge and the supply of new services would create fresh demands for beds.

In view of this rather troubled picture it is reassuring to have the word of the Secretary of State that: "When account is taken of the hospital accommodation provided in Scotland to meet wartime needs, it is obvious that there is now sufficient accommodation to form the foundation of a hospital system capable of providing for the needs of every person who requires hospital treatment."

Research on War Wounds

A subcommittee of the War Wounds Committee of the Medical Research Council, comprising representatives of Scottish hospital centres and teaching schools, has been set up to foster and co-ordinate research in war wounds and related problems in the field of casualty work. The membership of the subcommittee is Prof. J. R. Learmonth of Edinburgh (chairman); Prof. J. S. Young of Aberdeen University; Profs. R. C. Alexander and D. F. Cappel of Dundee; Profs. C. F. W. Illingworth and C. H. Browning and Dr. D. P. Cuthbertson of Glasgow; and Profs. Sir John Fraser and T. J. Mackie and Dr. C. P. Stewart of Edinburgh. Dr. J. M. Johnston will represent the Department of Health for Scotland. The secretary of the subcommittee is Dr. A. B. Wallace of the Department of Surgery, the University, Edinburgh.

ENGLAND AND WALES

York's New Municipal Hospital

The first half of York City's new Municipal General Hospital was opened recently by Alderman William Wright, who has served for twenty-nine years on the Health Committee, holding office as vice-chairman for seventeen years and chairman for four years. The new hospital, built on the most modern lines at a cost of nearly £100,000, was originally intended to accommodate 360 patients, but only half of the scheme could be put into operation under war conditions. Sir George Martin, chairman of the Leeds Health Committee and of the Yorkshire Regional Hospital Committee, said that the new institution would be very valuable in the regionalization of the hospital services of the county. Making the point that the one thing of real consequence in hospital administration was the patient, Sir George invited the York City Council to get rid of their distrust of the voluntary system and endeavour to make the best of both worlds; and, on the other hand, the voluntary hospital authorities should get out of their rather patronizing manner of speaking of municipal effort when praising the voluntary system. The country, he said, must have a proper working system, with complete co-operation between the two. Sir Francis Terry, chairman of the York County Hospital, who congratulated the City Council on building the new hospital, said that no one welcomed this addition more than the governors of the County Hospital.

London Chest Hospital

Some day, it is to be hoped, the story of the London hospitals under air attack will be told in a suitable volume. Meanwhile an interesting contribution to the literature of London's ordeal is forthcoming in the shape of a booklet on the London Chest Hospital (Victoria Park, E.2), which has been described by Ministry of Health officials as London's worst-bombed hospital in one night's attack. The hospital was founded ninety-three years ago in the City, but within a few years was moved out to Bethnal Green, where the foundation stone was laid by the Prince Consort in the year of the Great Exhibition. It became one of the leading centres for the treatment of chest diseases in Great Britain, with nearly 200 beds and a large out-patient department. The bombing, the results of which are illustrated in the booklet, took place on one night of last spring. It laid the north wing of the hospital practically in ruins, wrecked a part of the nurses' home, and completely demolished, among other buildings, the pathological department (which, incidentally, was started more than eighty years ago by the hospital's founder, Thomas Peacock, who worked here on congenital diseases of the heart and on the fatal disease of the lung known as "grinder's rot"). Although the patients on the night of the raid had elected to remain upstairs not one was killed; all were brought safely into the basement, and next day were transferred to their homes or to other hospitals. An examination of the building showed that in addition to the total destruction of certain parts, the roof had collapsed, and every window frame, door, and ceiling had been shattered. The brave story was continued in the work of reconstruction, for the out-patient department and attached clinics were quickly reorganized, and on the ninth day patients were again being treated. Despite further damage in another raid the wards were in use within four months. But a house at Camberley, which had been used as a sanatorium, has been secured, with accommodation for 30 to 35 patients, and this has relieved pressure on bed accommodation at the hospital and afforded a welcome change of environment for the nursing staff.

According to a correspondent of the *Journal of the American Medical Association*, psittacosis has recently appeared in the Paris area and has become a notifiable disease. There has also been an epidemic of scabies in Paris which has shown three periods of exacerbation, the first among the mobilized, the second at the time of massive evacuation, and the third at the return of the evacuated. Fats have become so scarce in France that ointments will soon become no longer obtainable.

Correspondence

Haemoglobinometry

SIR,—Martindale in the *Extra Pharmacopoeia* remarks, "Although the determination of the amount of haemoglobin is one of the most important of all the chemical tests of the blood, yet as a rule it is one which is determined with less care and by methods more inaccurate than those in use for any other constituents of the body." Most people, I imagine, will agree with this statement.

The two common methods in general use are the Tallqvist scale and Sahli's instrument. The Tallqvist scale is useful in giving an approximate idea of the degree of anaemia and in following the progress of a case under treatment. Few, however, I imagine, would use it for calculating the colour index or (what is perhaps more definite) in distinguishing between macrocytic and microcytic anaemias, the calculation of the mean corpuscular volume and the mean corpuscular haemoglobin content. Outside the laboratory the Sahli instrument is more commonly used for this. The Sahli instrument, of course, depends on the alteration of the haemoglobin to acid haematin. The change of colour here is continuous. About 95% of the change is attained in 10 minutes and it is finally complete in about 40 minutes. And here it seems to me that we get into difficulties.

For some time now, in estimating the colour index or the mean haemoglobin corpuscular content, I have wondered if my results were just what they ought to be. Sahli, in his original description of his instrument in *Diagnostic Methods* (1907), advises: "as soon as the mixture approaches a dark brown colour water is added." The Standing Committee on Laboratory Methods of Glasgow University advises in italics "exactly one minute." The makers of my instrument (Leitz) advise "shaking the tube for one minute and setting aside for 1 to 2 minutes before diluting." Whitby and Britton, in *Disorders of the Blood* (1939), advise a wait of 30 to 40 minutes before diluting. The graduation of my instrument in regard to the quantity of haemoglobin in grammes per 100 c.cm. of blood is the same as that shown diagrammatically in their book. I have made a few estimates with different patients, using first a 2-minute interval before diluting and repeating the experiment after waiting 40 minutes. The average reading after 2 minutes was 76% and for 40 minutes 94%, an average difference of 18%. In view of the above the Sahli method seems to me somewhat unsatisfactory. I have been using a Lovibond comparator with colour disks to compare with undiluted blood in a thin film in a special blood cell. This is graduated according to the Haldane scale, and in its lower ranges should give a closer approximation than the Tallqvist scale. This is a very handy instrument, but I find it difficult to get a close approximation, due possibly to the comparison between a clear glass and a suspension. Tintometer, Ltd., also make colour disks for the Haldane method and the acid haematin method. Incidentally, in the latter they allow 40 minutes for the final change of colour. These may be better than the undiluted blood method, but I have not tried them.

The main desideratum in the estimation of haemoglobin by colorimetric methods is that the change of colour should be rapid and complete. This might be accomplished by nitrites or other reagent giving a change to methaemoglobin, but I think the best solution is the Haldane method. I notice that Cecil Price-Jones in his book *Blood Pictures* mentions Haldane's method alone. To-day, of course, the difficulty with the Haldane method is in obtaining the necessary supply of coal gas. This difficulty, I think, could be overcome by the "sparklet" method. The quantity of carbon monoxide required is not large, so the sparklets could be small. The apparatus for releasing the gas could also be made small enough to go in a case without making it unduly bulky. With this and two standards, one for daylight use and one for artificial light, I think one would have a haemoglobinometer much more satisfactory in its results than the Sahli instrument.

These remarks are made from the viewpoint of the general practitioner and take no account of the more accurate methods used in laboratory technique.—I am, etc.,

KIRKMUIR, Nov. 5.

ROBT. D. CAMPBELL, M.B., Ch.B.

Fate of the Blood Lymphocyte

SIR,—In his review of *Lymphatics, Lymph, and Tissue Fluid*, by Drinker and myself (November 8, p. 653), your reviewer does me the honour of quoting verbatim some of my views on the defence function of the lymphatic apparatus, but has misrepresented somewhat my views on the fate of the blood lymphocytes. He states: "Yoffey thinks they go to the bone marrow to be the precursors of the red cells and granular leucocytes, but his arguments are not altogether convincing." Actually, while I believe that, on balance, the admittedly conflicting evidence at present available inclines to this view, it is far from proven. It certainly has not been proved to my own satisfaction, as indicated by several passages in the book, of which perhaps I might instance the following (p. 274): "The most careful histological studies of bone marrow have yielded inconclusive results, and the problem will probably not be solved to the satisfaction of everyone until new experimental lines of attack have been devised. If, for example, one could mark the lymphocytes by means of a vital stain, it might be feasible to collect a large number of lymphocytes in thoracic duct lymph, stain them, and reinject them into the blood. Examination of the bone marrow some hours later would show whether any of these marked lymphocytes had reached it. Possibly the statistical study of lymphocyte development used by Kindred (1940) may be further utilized."—I am, etc.,

Department of Anatomy, University of Bristol, Nov. 11. J. M. YOFFEY.

Dark-adaptation Tests and Vitamin A Deficiency

SIR,—Since many workers are using studies of dark adaptation as a means of detecting deficiency of vitamin A, it seems undesirable to allow the conclusions of Dr. E. Wittkower and his collaborators (October 25, p. 571, and November 1, p. 607) to pass unchallenged. In a group of admittedly psychopathic soldiers who complained of night-blindness they found only about one-third with subnormal dark adaptation. Arguing that the diet of these men must have been adequate in vitamin A, they conclude that "the value of dark-adaptation tests for the discovery of night-blind patients and as an indicator of vitamin A deficiency appears doubtful." This statement is clearly open to several important criticisms, which may be summarized as follows:

1. There is no doubt at all that poor dark adaptation is in fact associated with vitamin A deficiency. (a) Experimental diets deficient in vitamin A result in defective dark adaptation, which is reversed when the vitamin is taken. (b) Poor dark adaptation is commoner among individuals from the lower-income classes. (c) In almost all instances such poor dark adaptation is improved by the administration of vitamin A. To state, as do Dr. Wittkower and his colleagues, that the diet of their subjects was adequate in vitamin A is surely begging the question. It has been shown by numerous investigators that apparently normal diets are frequently not adequate in this vitamin, and that many individuals consuming them show poor dark adaptation which is cured by the administration of vitamin A.

2. A more serious criticism, however, is that the conclusions of Dr. Wittkower and collaborators are based on a *non sequitur*. They find that subjects suffering from severe psychological disturbance may complain of night-blindness, and that this may or may not be accompanied with demonstrably defective dark adaptation. Thus, they argue, the test cannot be used for the detection of deficiency of vitamin A. In other words, psychopathic individuals may show diminished powers of dark adaptation, and hence the measurement of this would probably detect mental instability rather than vitamin A deficiency. An analogy might perhaps best demonstrate the invalidity of this argument. A hysterical patient complains of defective vision or hearing. She finds it impossible to see the test type or to hear the ticking of a watch. Are we then to conclude that such visual or auditory tests cannot be used for the detection of organic blindness or deafness?

Subjective tests such as those for dark adaptation are, of course, dependent to a large extent on the co-operation and mental state of the individual being tested, and no one would deny the importance of bearing this in mind. The paper by

Dr. Wittkower and his co-workers serves a useful purpose in drawing attention to the psychological aspects of tests for night-blindness. In so far, however, as it attempts unwarrantably to minimize the usefulness of such tests for the nutritional worker, it is to be deplored.—I am, etc.,

Dunn Nutritional Laboratory, Cambridge, Nov. 7. JOHN YUDKIN.

Blood Transfusion and Syphilis

SIR,—The number of persons now receiving blood transfusion is increasing due both to war conditions and also to a natural extension of the practice. The transmissions of syphilis by this means are, as at present recorded, relatively very few, but there may be more cases not reported for obvious reasons. Further, it would seem that war conditions have increased the number of persons suffering from syphilis.

The risks would lie in two classes of blood transfusion: (1) that of whole blood immediately used, and (2) perhaps in stored whole blood used early. The Wassermann, or any other serological safeguard, cannot entirely eliminate the risks of transmission. There might be, for instance, cases (a) where the person tested is incubating the disease. (b) where a chancre is present but the case is in an early sero-negative stage, and (c) where a person has acquired the disease after being tested and prior to being called upon to give his blood. The expense and time consumed in serological tests are considerable. The administration of whole blood practically immediately after withdrawal from the donor would be, in an infected donor, a very grave matter, especially in the early stages of syphilis referred to above, and in which the serological tests might be negative during the septicaemic stage.

In regard to stored blood it is a fact that *Treponema pallidum* is stated to be able to survive for considerable periods in various materials from infected persons and animals. Reference to Volume 8 of the *System of Bacteriology* will give some data on this matter. We do not know of any work which has been conducted on the survival of *Treponema pallidum* under refrigerator storage conditions.

From the above considerations it appears to us that the work of Kast, Peterson, and Kolmer,¹ and especially a recent publication by Eichenlaub *et al.*,² are of premier importance. The latter group of workers used mapharsen to rid infected citrated blood of *Treponema pallidum*. They found that 0.01 gramme per 500 c.cm. of citrated blood was amply sufficient for the purpose, and based this finding largely on work on rabbits which were exposed to infected material without the addition of the arsenical mapharsen. Mapharsen is of relatively low toxicity, and, in the amount suggested, the dose is so small as to be most unlikely to affect even a very seriously ill person. Further, the drug is directly antitreponemal and does not require chemical action to form arsenoxide. Contraindications might arise in cases where the recipient was suffering from (1) haemorrhagic purpura, (2) exfoliative dermatitis, (3) hepatic disorders, and (4) renal disease. The cost of sterilizing against *Treponema pallidum* in 500 c.cm. of citrated whole blood would be relatively small.

While in no way claiming to possess any expert knowledge in regard to blood transfusion, the method advocated by Eichenlaub and his collaborators would appear to us to add yet another safeguard to the recipient of a blood transfusion. We venture cordially to congratulate the above workers, and also to suggest that the value of the method shall be considered by those more qualified than ourselves to judge of its practicability and utility.—We are, etc.,

November 10.

Possibility of Malaria in Britain

SIR.—Dr. I. F. Mackenzie's letter (November 8, p. 668) is a timely reminder to general practitioners and those temporary Service medical officers who have little or no experience of malaria. As a result of the technique of investigation, treatment, and control evolved since the last war, I think it would

be fair to say that there is less risk of oversight on the part of regular medical officers of all Services.

Malaria is a potential danger wherever "carriers" and anopheline mosquitoes coexist, but certain areas were especially dangerous in the last war. Cases of indigenous malaria have occurred in certain areas after every war in which troops have been exposed to infection over-seas, and the present war will probably be no exception. Thanks to the knowledge with which we are now armed, and given early diagnosis and efficient treatment of indigenous cases, there is little danger of the large ever reaching serious proportions.

The following table is taken from *Observations on Malaria* (H.M.S.O., 1919):

Carriers of Malaria under Treatment during May to September, 1918

1918	Sheppey		Lydd		Sandwich	
	In Hospital	Not in Hospital	In Hospital	Not in Hospital	In Hospital	Not in Hospital
May	—	491	—	74	13	7
June	—	552	12	84	14	11
July	—	550	7	24	10	47
August ..	—	349	Nil	23	8	17
September ..	—	46	1	33	6	32

The above figures relate to men from over-seas. During 1918 sixty-one cases of indigenous malaria in serving soldiers were reported. Each case was carefully investigated; none had a previous malarial history and most of them had never been out of this country. The indigenous character of the infection was established in every instance. Forty-two cases occurred in the Sheppey, Isle of Grain, Sandwich, and Lydd areas, and the remaining nineteen were distributed between Aldershot (4), Suffolk (6), Norfolk (2), Essex (2), Sussex (1), Leicester (1), Nottingham (1), Lincs (1), and Herts (1). Twenty-nine foci of infection were located.

References to "ague" in the literature of the sixteenth century make it clear that malaria was endemic in England at that time. It is now practically, if not quite, extinct, not because of any sanitary measures specifically designed for its eradication, but as a fortuitous result of the improvement in the general sanitary condition of the country.

Introduction of a natural reservoir of infection in the form of malaria patients from over-seas certainly supplies what Dr Mackenzie calls "the missing link"; but Service authorities are fully alive to the risk to the civil population thereby entailed, and every care is taken to render patients parasite-free before they are "turned loose" on the uninfected anopheline. It must not be forgotten that even in peacetime there is a continual traffic of infected civilians on leave from over-seas, who are usually far less carefully supervised.

It is doubtful whether medical officers of health do all they might to discover and eradicate anopheline breeding-places. I have in mind certain stagnant pools and miles of derelict canals which I have myself dipped and proved to be prolific nurseries of anopheline larvae.—I am, etc.,

Brookwood, Nov. 9.

H. M. STANLEY TURNER

"Euglamide" in Treatment of Burns

SIR.—In the *Journal* of March 29 (p. 469) we reported the results obtained in burns treated with a glycerin sulphamide paste termed "euglamide." Briefly these results appeared to indicate that the use of the paste led to prompt healing and that it might be of value in the treatment of third degree burns and in burns of the hands and face. Work on this subject has been continued, and we have made several alterations in the dispensing, though the principle of using a water-soluble sulphamide in glycerin has been retained.

(1) Work which one of us (J. M. R.) has carried out in collaboration with Major G. I. Scott has shown that a solution of sodium sulphacetamide (supplied in a 30% solution by E. Schering Ltd.) exhibits a much higher chemotherapeutic activity than a similar solution made by dissolving the solid material (supplied by the same firm) in water. For this reason we now use the 30% solution in making up the euglamide.

(2) By making up the paste with "eucerin" (a proprietary ointment base made from the oxycholesterin of wool fat and

¹ *Amer. J. Syph. Gon. ven. Dis.*, 1939, 23, 150.

² *Arch. Derm. Syph.*, 1941, 44, 441.

paraffin, supplied by Herts Pharmaceuticals, London) instead of kaolin and cod-liver-oil, a material is obtained which penetrates more readily all parts of the injured area and shows no tendency to dry or cake.

(3) Higher concentrations of the sulphonamide have been employed and the paste at present favoured is one which contains 10% of the sulphonamide in its liquid phase. The formula of this material is:

30% solution of sodium sulphacetamide (albicid soluble)	135 c.cm.
Distilled water	65 c.cm.
Glycerin	200 c.cm.
Eucerin	400-450 grammes

The liquid constituents are mixed together in a mortar or other suitable receptacle and the eucerin is then gradually added and mixed until a suitable paste forms.

The results so far obtained with this "euglamide" have been satisfactory, though sufficient data have not yet been gathered to justify a communication on the subject. At the same time we thought it worth while to report briefly our progress in this investigation.—We are, etc.,

Operation for Reduction of Fractures of the Os Calcis

SIR,—Surgeon Lieut.-Commander W. G. Campbell (November 8, p. 651) has not described a new method of treatment for certain types of fracture of the os calcis. The method was first described to me by Böhler in 1935, and he learnt it from, I think, Kirschner. Further, the method is described and illustrated in Watson Jones's most excellent book (first edition, p. 625, Figs. 951 and 952). It would be interesting to know its true originator.

From an extensive experience of manipulative reduction of fractures of the os calcis by a pin placed in the axial plane of the posterior fragment I can say this: (1) it is a suitable method for comminuted fractures of the os calcis with a large posterior fragment associated with depression of the posterior articular facet of the os calcis; (2) after manipulation, if too much force has not been used, the radiograph in the lateral view shows an exact anatomical reduction; (3) this exact reduction is frequently not confirmed in the axial (plantar-dorsal) radiograph of the os calcis, because manipulation by the axial pin does not correct the displacements associated with fractures of the sustentaculum tali and the buckling of the outer wall of the os calcis. When an exact reduction has been confirmed by two-plane radiography it is wise to incorporate the pin in the plaster for a period of six weeks, otherwise with such a comminuted fracture the reduction will be lost. I have experimented with various designs of pin and methods of manipulation, and from that experience I can assure Commander Campbell that the method is not simple and that it does require more than a minimum of surgical skill.—I am, etc.,

Birmingham, Nov. 10.

WILLIAM GISSANE, F.R.C.S.

SIR,—I read with interest the description by Surgeon Lieut.-Commander W. Gordon Campbell of a simple reduction of certain fractures of the os calcis. I can agree whole-heartedly with him as to the simplicity and efficacy of this manoeuvre with regard to the overcoming of the pull of the tendo Achillis in most of these os calcis fractures. I have been accustomed to using this simple spiking of the posterior fragment associated with lateral compression and fixation in plaster during the past four years, and regard it as being one of the most satisfactory ways of regaining the normal shape of the foot. I have never known any harmful sequelae, and not one patient has complained of the small scar which was left at the back of the heel.

My experience has been similar to that of most people, that while there are many methods of re-establishing the shape of the foot, these methods have little effect in restoring the movements of the subtalar joint. This simple operation can be carried out to give a good shape to the foot after a great majority of compression fractures of the os calcis.

After restoring the depth of the heel and accentuating the normal arch of the foot, I believe that the most important next

step is that the patient should be fitted with a moulded arch support in order to relieve the ligamentous strain which is inevitable when he starts walking again.—I am, etc.,

Nottingham, Nov. 11.

A. N. BIRKETT.

Endoscopic Resection of the Prostate

SIR,—I was much interested in Mr. H. T. Cox's note on endoscopic resection of the prostate (October 25, p. 583). It would be a pity if the idea gained ground that by fitting a check to the resectoscope the external sphincter could, therefore, be certainly protected. I do not believe this on the following grounds. (1) In the course of a resection frequent reference must be made to the verumontanum as a guide to the sphincter. It is manifestly impossible to retain the resectoscope in a fixed position if an efficient operation is to be carried out. (2) It appears to me to be bad practice to cut if haemorrhage obscures the view. (3) In my experience of some hundreds of cases, using both the McCarthy resectoscope and the Gershom Thompson punch, intra-urethral (and intravesical) projection of the prostate form the majority. Consequently the prostatic urethra varies in length from one side to the other, and where a middle lobe exists measurement by any gadget must be entirely misleading. Moreover, when a prostate has been incised it tends to shrink, so that any measurement taken at a first resection is unlikely to be of any value in a repeat performance.

It is difficult to follow Mr. Cox's reasoning in his recommendation "to leave the most prominent part of the prostatic ledge at the internal meatus." Surely the first task is to expose the fibres of the internal sphincter all round the bladder neck. These fibres are easily identifiable, and such exposure permits prostatic tissue to prolapse more easily into the urethra.

No, Sir, the great trouble with the loop resectoscope is the difficulty of using it. The visual field is often poor, and structures are not seen in their natural size or position. The instrument is delicate and temperamental, and the smallest piece of clot adhering to the distal end means complete obscurity of the field of operation. May I suggest to Mr. Cox that he transfer his affections to the Gershom Thompson direct-vision punch, when his fears of "black-outs" will vanish. After all, the world's best work in the field of this problem has been done by Gershom Thompson, Emmet, and their colleagues.—I am, etc.,

Newcastle-upon-Tyne, Nov. 10.

W. E. M. WARDILL.

Sulphonamides for Ophthalmia Neonatorum

SIR,—The treatment of ophthalmia neonatorum has been greatly simplified in the past few years by the introduction of sulphapyridine and sulphathiazole. The usefulness of these drugs in this dangerous disease is not widely enough known, and even recent textbooks do not stress sufficiently their use in this connexion.

Either sulphapyridine or sulphathiazole can be used; the dose recommended is 0.125 grammes (1/4 tablet) three-hourly for the first twenty-four hours, then four-hourly for the next twenty-four hours, and, finally, six-hourly for four days in all. The drug is given crushed in sweetened water and is well tolerated, but should be stopped if it causes vomiting or should a diffuse rash appear. The response is invariably prompt and satisfactory; in twenty-four hours the oedema of the lids will be much less, and in forty-eight hours the discharge will have almost ceased and the eyes are open. I have treated many cases in the last three years with most satisfactory results, the infants being detained in hospital not more than seven days.

The advent of the sulphonamide compounds has rendered local treatment of the infected eyes unnecessary. The simple instillation of medicinal paraffin to prevent the lids sticking is all that is required. The special nurse and frequent irrigation are no longer necessary. Recent experiences would seem to point to the fact that some practitioners still rely solely on local treatment to the eyes. This is no longer justifiable, and it is of the utmost importance that either of the compounds mentioned be administered as soon as the signs of ophthalmia appear, and thus any permanent damage to the eyes will be prevented.—I am, etc.,

WILLIAM J. CLANCY,
Obstetric Officer.

City General Hospital, Sheffield, Nov. 7.

blanket is arranged to hang down on either side of the stretcher to confine the heat. With reasonable care this method is free from danger and economizes space. It is important to bear in mind that blankets between the patient and the stretcher during transport are just as important as those placed over them.—I am, etc.,

Leeds, Nov. 12.

H. COLLINSON.

SIR,—Dr. R. L. Kitching (November 8, p. 668) suggests that as a rule such cases should be sent to a first-aid post. There are several objections to this: (1) On the spot (the first-aid party man may not have discovered either the shock or the condition causing it. (2) In most cities and towns the hospital should be as near as a first-aid post for early treatment. (3) For the proper treatment of cases of shock there should be a resuscitation room with a constant heated temperature of not less than 70° F.; this does not exist at any first-aid post that I am aware of (some hospitals probably also have not got this constant temperature). (4) To carry out the excellent suggestions he makes would require a special trained staff of nurses (not auxiliaries); of what use would the auxiliary nurse be who passes an examination on the signs, symptoms, and treatment of greenstick fracture, fainting, varicose veins, and types of slings, and *truly nothing more*? (5) If the case is one of internal haemorrhage or other condition demanding immediate operation there would be the added danger of delay against a possible recovery.

Since the first thing a shocked patient requires is heat (unless the shock is from haemorrhage or pain) then this is where a mobile unit is of greatest value: it can do all that is necessary. I am not sure that the present policy of keeping them at posts is altogether right, as one would require certain information from hospitals—whether a given number of cases of shock if they had had the required treatment on the spot of the injury would have recovered. I certainly am of the opinion that a mobile unit should go out at all major "incidents" as a routine. There is a tendency to rely too much on first-aid parties, whereas more mobile units with their doctors, trained nurses, and full equipment are likely to secure more successful results with all types of injuries. The idea, mooted in another quarter, to put the casualty treatment in the hands of a particular association would be calamitous. The suggestion of keeping blankets warm at first-aid posts is excellent, and this should be done; but what is required is to bring these blankets warm to the sites of injuries, and this can be done in a mobile post with a double-lined tin box with hot water between the two linings.—I am, etc.,

Nov. 10.

A. G. N.

Mobile Units

SIR,—Of your many correspondents on this subject some appear to have waited patiently for the ideal conditions to set up a mobile aid-post as originally planned, and in their disappointment have condemned the units as a useless extravagance; most of the others (I exclude the writers from rural areas whose elaborate coaches are designed for a different need) appear to have seen no alternative but to go out with one or two nurses in their own cars and send back for the full unit if circumstances demanded.

In this borough we hit on a compromise which seems to me to combine many of the advantages of both the full mobile and the light car and which is worth recording. My colleague, Dr. L. J. Soutter, and I, who were in September, 1940, responsible for the borough's two mobile units, were very quickly convinced that to await the conditions for which we, in common with other mobile unit doctors, had trained ourselves and our teams would mean an indefinite waste of trained and eager personnel; we therefore obtained permission, while keeping one van with its team always ready to function as a full unit, to convert the other into what was christened the "incident squad." The heavier equipment was removed, only that likely to be required for strictly first-aid purposes being retained, and the van (a 30-cwt. Morris) was staffed by a doctor, a sister, and three auxiliary nurses, each one being provided with a haversack, over the stocking and packing of which great care was taken; the haversacks were packed exactly alike so that each nurse knew just what her haversack contained and could find anything in it in the dark. The "incident squad" was out between twenty and thirty times last winter, and did some very useful work.

The scheme has all the advantages of the light car method while having behind it a variety of equipment which a car cannot carry; it also allows for a larger number of nurses than a car can carry and for the keeping of records. No two "incidents" are exactly alike, and it is wise to keep an open mind as to how to act on arrival, but we have been able to deal satisfactorily with trapped casualties, to attend a certain number of the cases at major incidents without delaying the quick evacuation of the remainder by stretcher-bearers, and finally, when the serious cases have all been evacuated, to make a canvass of the neighbouring houses, which very often discloses a number of minor casualties who would otherwise receive no attention until the following morning at the earliest. If no further orders have been received from Control, a stop is made on the return journey at any rest centre which has been opened; in addition to finding minor casualties here, we have twice found epileptics whose supply of luminal has been destroyed, and three times we have found diabetics who have lost their insulin; both these drugs are now carried in the vans.

The two units undertake "incident squad" work alternately for a week at a time, and the girls are encouraged to use their initiative and, when necessary, work on their own. Nothing has been more gratifying than to see how the raw recruits of two years ago are acting to-day as cool and confident individualists.—I am, etc.,

Hornsey, Nov. 13.

G. F. RIDGEN.

Practical Results of Diphtheria Immunization

SIR,—I have read the letter from Dr. Ralph Weaver, M.O.H. for Brisbane (November 8, p. 669), in which he claims to have achieved striking results in the reduction of diphtheria incidence in Brisbane following a three-and-a-half-years immunization campaign. He bases his claim (a) upon the figures for nineteen months (1940 and part of 1941), and (b) after having immunized 22,912 children out of a population of over 320,000.

I would suggest that these data are far too small to justify Dr. Weaver's optimism. It would be easy to cite cities where immunization has been carried out quite as thoroughly as and over a longer period than in Brisbane, but where, so far from a reduction, an actual increase in diphtheria has occurred. Yet it would be quite unjustifiable to assert that this was the result of the immunization campaign. Both the incidence and mortality from diphtheria fluctuate notoriously from year to year, and it will only injure the cause of immunization if claims to have achieved results are put forward too hastily. I would suggest to Dr. Weaver that he would be well advised to warn his local authority that diphtheria incidence in Brisbane may again go up in spite of his immunization campaign, and that mortality may increase if the type of the disease changes, rather than talk at this early stage about "a diphtheria-free Brisbane being not far distant."

For myself, I have during the past twelve months personally immunized nearly 5,000 children in a population of only 40,000, a much higher proportion and in a shorter time than Dr. Weaver has accomplished in Brisbane, but I am not so sanguine as he is about abolishing diphtheria.—I am, etc.,

Leicester, Nov. 7.

C. KILLICK MILLARD.

Vaccinia as a Complication of Vaccination

SIR,—According to official statistics for the five years July 1, 1932, to June 30, 1937, public vaccinators in England and Wales reported 1,026,588 vaccinations. In the same period there were recorded fifteen definite cases of vaccinia and eleven doubtful cases, with one death. If the doubtful cases are included this gives an incidence of 1 in 39,484 vaccinations and a death rate of one in over a million vaccinations. In view of the rarity of this complication it would seem worth while to put on record a recent case, which unfortunately had a fatal termination.

On October 2, 1941, at the request of the parents, I vaccinated a boy aged 3½ and his baby sister aged 7 weeks. I usually prefer to vaccinate babies when three to five months old, but this baby seemed to be perfectly healthy and there was no reason to anticipate any abnormal reaction. The result in the case of the boy was absolutely normal and satisfactory with no complications whatever.

A week after vaccination I found that the baby had developed at the site of vaccination on the lateral aspect of the left thigh one

any specific effect other than diuresis. The diluting the urine, will reduce the percentage of urine the removal of oedema may so improve the general and tissue circulation that the diabetic metabolism is elaborated thereby. Without knowing all the details or a full appreciation of his case, we suggest that the factors, and especially the latter, explain the improvement.—We are, etc.,

of Burns and Wounds by Envelope Method

last! The papers on the subject of the treatment d wounds (July 5 and 12) and your leader of the resent a complete review of this problem, which I with great interest. At last there is emerging a better on of all the difficulties and of a principle upon may be overcome. This principle includes adequate cleansing and disinfection, prevention of secondary and the provision of drainage—in other words, Active movement of the injured part, even if it be advised, in spite of the opinion of others that such apt to light up infection. What are we to think? do not admit this danger. Fixation or movement secondary in importance if secondary infection be We can do just what the case dictates with this

manner in which the principle is to be applied no limitations when he said: "For sure I am that, ch the means of carrying out the antiseptic prin- come to vary from those which we now use, the lself will certainly be ultimately recognized as the ant of all those that shall guide the practice of the sooner our profession is aware of this, the be for suffering humanity." For the benefit of

body cells and fluids. With regard to the dressing of the wound he said: "After the first dressing, the object which I always aimed at is to have the material in contact with the exposed tissues approximate as close as possible to the perfectly bland and neutral character of the healthy tissues." So in a devious, tortuous, and difficult way we come "back to Lister."

However promising the results may appear which follow the closed contact plaster method and that of the envelope, I predict their passing in favour of a complete and secure application of the antiseptic principle, contending that neither of those in use complies with its requirements and both smack too much of the same old trial-and-error ways which have been our expedients through the ages. I cannot refrain from protesting that any method introduced to the profession which makes it obligatory in its adoption to use but one reagent, proprietary or not, is invidious. Yesterday it was "dettol," to-day it is "milton"; both are valuable preparations, but I do not feel dependent on either of them. Any reliable antiseptic will serve, and this is as it should be; all of them or any one will suffice in applying the antiseptic principle, "and the sooner our profession is aware of this, the better will it be for suffering humanity."—I am, etc.,

A. C. F. HALFORD, M.D., F.R.A.C.S.
Brisbane, Queensland, Sept. 18.

Treatment of Wound Shock in First-aid Posts

SIR.—In your issue of November 8 Dr. R. L. Kitching makes some suggestions with regard to the equipment of first-aid posts for the purpose of warming up seriously injured patients.

In the first place I should like to join issue with him when he expresses the view that cases should not be sent direct to hospital, but should be treated for shock in a first-aid post "until they are fit for operation." Experience in Spain, in London, and some of our larger cities has shown that the sooner the patient reaches hospital the better, and that in serious cases the patient is usually sent direct from the incident without going to a first-aid post. Elaborate first aid is undesirable and is, in fact, impossible under the conditions existing; it is usually dark and the patient covered with dirt, soot, and brick dust; all that can be done is to splint or control a fractured limb, apply, but very rarely, a tourniquet, and cover the stretcher and the patient with blankets. It is a question whether even dressings over the wound are of any particular advantage unless for the purpose of controlling haemorrhage, and the application consumes valuable time. In many hospitals where large numbers of cases had to be dealt with few dressings were applied in the receiving room, but the patients were rapidly classified according to the severity of the injury and sent to the appropriate wards. Fitness for operation can only be decided by an experienced surgeon or physician at the casualty hospital, and resuscitation carried out at a first-aid post may be negated by a subsequent journey in an ambulance.

The foregoing applies, of course, to casualties occurring in a city where a hospital is comparatively close, and I agree with Dr. Kitching that where, as in his case, the first-aid post is separated from the hospitals by eight or twelve miles, the post can play an important part in combating shock in the interval between reception of the cases and the arrival of the ambulances. Judgment will be needed in deciding whether a case will receive more benefit by being kept for a short time in the post or by being sent as quickly as possible to hospital.

There is no question that warmth, posture, and the giving of fluids are of prime importance in combating shock, but I think that the method of heating described by Dr. Kitching is unnecessarily elaborate. A good supply of warm blankets and hot bottles is essential, but I would suggest that the method of warming patients adopted in the last war by regimental first posts and field ambulances is much simpler and equally effective. The stretcher is supported on trestles, and on the floor beneath a primus stove is placed with a sheet of metal on top. A

blanket is arranged to hang down on either side of the stretcher to confine the heat. With reasonable care this method is free from danger and economizes space. It is important to bear in mind that blankets between the patient and the stretcher during transport are just as important as those placed over them.—*am, etc.,*

Leeds, Nov. 12.

H. COLLINSON.

SIR,—Dr. R. L. Kitching (November 8, p. 668) suggests that as a rule such cases should be sent to a first-aid post. There are several objections to this: (1) On the spot the first-aid party may not have discovered either the shock or the condition causing it. (2) In most cities and towns the hospital should be as near as a first-aid post for early treatment. (3) For the proper treatment of cases of shock there should be a resuscitation room with a constant heated temperature of not less than 70° F.; this does not exist at any first-aid post that I am aware of (some hospitals probably also have not got this constant temperature). (4) To carry out the excellent suggestions he makes would require a special trained staff of nurses (not auxiliaries); if what use would the auxiliary nurse be who passes an examination on the signs, symptoms, and treatment of greenstick fracture, fainting, varicose veins, and types of slings, and *truly nothing more?* (5) If the case is one of internal haemorrhage or other condition demanding immediate operation there would be the added danger of delay against a possible recovery.

Since the first thing a shocked patient requires is heat (unless he shock is from haemorrhage or pain) then this is where a mobile unit is of greatest value: it can do all that is necessary. I am not sure that the present policy of keeping them at posts is altogether right, as one would require certain information from hospitals—whether a given number of cases of shock if they had had the required treatment on the spot of the injury would have recovered. I certainly am of the opinion that a mobile unit should go out at all major "incidents" as a routine. There is a tendency to rely too much on first-aid parties, whereas more mobile units with their doctors, trained nurses, and full equipment are likely to secure more successful results with all types of injuries. The idea, mooted in another quarter, to put the casualty treatment in the hands of a particular association would be calamitous. The suggestion of keeping blankets warm at first-aid posts is excellent, and this should be done; but what is required is to bring these blankets warm to the sites of injuries, and this can be done in a mobile post with a double-lined tin box with hot water between the two linings.—*I am, etc.,*

Nov. 10.

A. G. N.

Mobile Units

SIR,—Of your many correspondents on this subject some appear to have waited patiently for the ideal conditions to set up a mobile aid-post as originally planned, and in their disappointment have condemned the units as a useless extravagance; most of the others (I exclude the writers from rural areas whose elaborate coaches are designed for a different need) appear to have seen no alternative but to go out with one or two nurses in their own cars and send back for the full unit if circumstances demanded.

In this borough we hit on a compromise which seems to me to combine many of the advantages of both the full mobile and the light car and which is worth recording. My colleague, Dr. L. J. Soutter, and I, who were in September, 1940, responsible for the borough's two mobile units, were very quickly convinced that to await the conditions for which we, in common with other mobile unit doctors, had trained ourselves and our teams would mean an indefinite waste of trained and eager personnel; we therefore obtained permission, while keeping one van with its team always ready to function as a full unit, to convert the other into what was christened the "incident squad." The heavier equipment was removed, only that likely to be required for strictly first-aid purposes being retained, and the van (a 30-cwt. Morris) was staffed by a doctor, a sister, and three auxiliary nurses, each one being provided with a haversack, over the stocking and packing of which great care was taken; the haversacks were packed exactly alike so that each nurse knew just what her haversack contained and could find anything in it in the dark. The "incident squad" was out between twenty and thirty times last winter, and did some very useful work.

The scheme has all the advantages of the light car method while having behind it a variety of equipment which a car cannot carry; it also allows for a larger number of nurses than a car can carry and for the keeping of records. No two "incidents" are exactly alike, and it is wise to keep an open mind as to how to act on arrival, but we have been able to deal satisfactorily with trapped casualties, to attend a certain number of the cases at major incidents without delaying the quick evacuation of the remainder by stretcher-bearers, and finally, when the serious cases have all been evacuated, to make a canvass of the neighbouring houses, which very often discloses a number of minor casualties who would otherwise receive no attention until the following morning at the earliest. If no further orders have been received from Control, a stop is made on the return journey at any rest centre which has been opened; in addition to finding minor casualties here, we have twice found epileptics whose supply of luminal has been destroyed, and three times we have found diabetics who have lost their insulin; both these drugs are now carried in the vans.

The two units undertake "incident squad" work alternately for a week at a time, and the girls are encouraged to use their initiative and, when necessary, work on their own. Nothing has been more gratifying than to see how the raw recruits of two years ago are acting to-day as cool and confident individualists.—*I am, etc.,*

Hornsey, Nov. 13.

G. F. RIDGEN.

Practical Results of Diphtheria Immunization

SIR,—I have read the letter from Dr. Ralph Weaver, M.O.H. for Brisbane (November 8, p. 669), in which he claims to have achieved striking results in the reduction of diphtheria incidence in Brisbane following a three-and-a-half-years immunization campaign. He bases his claim (a) upon the figures for nineteen months (1940 and part of 1941), and (b) after having immunized 22,912 children out of a population of over 320,000.

I would suggest that these data are far too small to justify Dr. Weaver's optimism. It would be easy to cite cities where immunization has been carried out quite as thoroughly as and over a longer period than in Brisbane, but where, so far from a reduction, an actual increase in diphtheria has occurred. Yet it would be quite unjustifiable to assert that this was the result of the immunization campaign. Both the incidence and mortality from diphtheria fluctuate notoriously from year to year, and it will only injure the cause of immunization if claims to have achieved results are put forward too hastily. I would suggest to Dr. Weaver that he would be well advised to warn his local authority that diphtheria incidence in Brisbane may again go up in spite of his immunization campaign, and that mortality may increase if the type of the disease changes, rather than talk at this early stage about "a diphtheria-free Brisbane being not far distant."

For myself, I have during the past twelve months personally immunized nearly 5,000 children in a population of only 40,000, a much higher proportion and in a shorter time than Dr. Weaver has accomplished in Brisbane, but I am not so sanguine as he is about abolishing diphtheria.—*I am, etc.,*

Leicester, Nov. 7.

C. KILICK MILLARD.

Vaccinia as a Complication of Vaccination

SIR,—According to official statistics for the five years July 1, 1932, to June 30, 1937, public vaccinators in England and Wales reported 1,026,588 vaccinations. In the same period there were recorded fifteen definite cases of vaccinia and eleven doubtful cases, with one death. If the doubtful cases are included this gives an incidence of 1 in 39,484 vaccinations and a death rate of one in over a million vaccinations. In view of the rarity of this complication it would seem worth while to put on record a recent case, which unfortunately had a fatal termination.

On October 2, 1941, at the request of the parents, I vaccinated a boy aged 3½ and his baby sister aged 7 weeks. I usually prefer to vaccinate babies when three to five months old, but this baby seemed to be perfectly healthy and there was no reason to anticipate any abnormal reaction. The result in the case of the boy was absolutely normal and satisfactory with no complications whatever.

A week after vaccination I found that the baby had developed at the site of vaccination on the lateral aspect of the left thigh one

typical vesicle. Two days later there appeared a vesicle on the front of the left ankle, and this was the precursor of a succession of vesicles occurring mainly on the limbs, with a few on the face and very few on the trunk. The distribution was identical with that of variola, and the stages of the eruption also corresponded. The baby's general condition remained good for five days after the appearance of the vesicle on the ankle. By this time most of the rash was in the pustular condition, and the evening temperature became elevated to the region of 101° F. About this time two vesicles appeared on the tongue. Small doses of sulphamylamide (a quarter of a tablet every four hours) with bicarbonate of soda were given, but after twenty-four hours this had to be stopped because of diminution in the renal output.

By the morning of October 18, owing largely to the lingual involvement, there was difficulty in swallowing, and rectal injections of glucose solution were begun. The baby and mother were admitted to hospital for a continuation of the rectal injections, to which were added two or three minims of coramine. It was hoped that by tiding the baby over the dysphagic phase she might in the course of a day or two be able to resume swallowing and so maintain her body fluids. The prognosis, however, became less favourable by the appearance of haemorrhage into some of the spots. In hospital she became gradually weaker, and died in the early morning of October 19.

The guaranteed calf lymph employed was obtained in two small capillary tubes and was quite fresh. As the boy was not at all adversely affected it is to be assumed that no fault can be attached to the lymph and that the occurrence of vaccinia and the subsequent death were traceable to hypersusceptibility on the part of the baby. It is a matter for speculation whether, in the absence of vaccination, this hypersusceptibility might have appeared later in life in the presence of any other infection.—I am, etc.,

Corbridge, Nov. 12.

J. N. TURNBULL, M.B., F.R.C.S.Ed.

Treatment of Scabies

SIR,—I have read with interest the correspondence in the *Journal* on the prevention and treatment of scabies.

Most general practitioners are, I think, agreed that treatment with benzyl benzoate is the method of choice. Unfortunately, in an area like my own, where cases are numerous, this preparation is not always obtainable. I have regularly applied the treatment described by Dr. E. W. Prosser Thomas (November 1, p. 631) with satisfactory results. Each patient is supplied with the necessary amount of 10% sulphur ointment, and instructed to return after three days of intensive treatment, bringing with him, in order to minimize the risk of a sulphur dermatitis, any unused ointment. The patient is also given typed instructions as to procedure, similar to those issued by Dr. Prosser Thomas.

I am quite sure that without proper disinfecting of garments and bedding recurrence of the condition and further infection of contacts take place not infrequently. My experience in this respect has been interesting. In the area of my practice there are two adjoining authorities in whose area the majority of these cases occur. One authority, on the morning of the fourth day after treatment has commenced, sends for and removes all clothing and bedding, returning them to the house of the patient on the same evening after thorough disinfecting. In the case of the other authority no facilities exist for this purpose. The majority of my cases have occurred in the area of the former authority and a recurrence has been rare. In the case of the authority where no assistance is given, and the unfortunate household have to do their best to disinfect bedding and clothing, reinfection is a common occurrence.

Until notification of this disease is compulsory and the prevalence of the condition is brought home to those in authority, there would appear to be little chance of stamping out this unpleasant condition.—I am, etc.,

Warkworth, Northumberland, Nov. 6.

R. E. MOYES.

Post-war Medicine

SIR,—The correspondence on State Medical Service shows neither sign of termination nor of contribution to progress. I presume (although perhaps I am unduly optimistic) that the supporters of a State Medical Service, like the supporters of private practice more or less in its present form, are persons who desire to attain the best possible service to the community with reasonable security and remuneration for

the doctor. Surely, then, it is necessary to determine what is wrong with the present state of affairs, because to propose a doctrinaire solution of all difficulties is no part of medicine, even if it is characteristic of much that passes as politics. We get no further by vituperation, even when it is in the mild form of an accusation that we doctors have a "vested interest in disease." One becomes inured to the sloppy mode of expression that characterizes most of the writing on State Medical Service, but let us never become reconciled to it.

It is alleged that the practice of medicine is "sick"; let those who say so indicate the nature and aetiology of the maladies that afflict it. If they can do so it will then be time enough to discuss the cure; but let it be remembered that there is a very limited pharmacopeia (according to the supporters of State Medical Service): either leave things in what is alleged to be their present horrid state or turn the medical world inside out. The fact that there are those among us who prefer whole-time appointments (and do their best work in them) while others prefer "piece-work" does not prevent these gentry from advocating a Procrustean bed into which the second group must be forced.

Mr. Wilfred Shaw's fourth point (*Journal*, November 8, p. 665) that we should plan a medical Utopia and then work towards it is admirable, but we can only work with the material that is available. In the name of all that is sensible let us, as doctors, avoid the stupid view that we should dislike any Utopia (and indeed deny that it is a Utopia) unless it is attained by the means that our preconceptions have led us to believe are the only decent methods.

The stupidities into which the scholastic philosophers were led by their adherence to the deductive method should surely be a warning to us to stick to the experimental route that has led our profession so successfully to its present state. No general principle can have greater strength than the observations on which it is based (unless the supporters of a State Medical Service regard their first principle as being divinely inspired); and we are therefore not bound to accept any one view to the exclusion of all others.

The questions are, What is wrong with medicine to-day? and, What shall we do about it? This is very different from the doctrinaire statement that what is wrong with medicine is private practice, and that all that is needed is to do away with that.

In conclusion I should like to inquire what remarkable changes we are to expect if a State Medical Service comes into being. Is there to be less disease; is research to progress more rapidly and more successfully; or is all we shall gain but the status of civil servants?—I am, etc.,

London, N.W.1, Nov. 8.

A. PINLEY.

SIR,—Mr. Wilfred Shaw's letter (November 8, p. 665) is provocative, as no doubt he meant it to be, and I hope that the implications of paragraph 1 will not pass unnoticed.

Far-reaching political changes are inevitable after this war, but whatever political party is in power will most certainly regard the future health of the people as a political issue of the first magnitude, and to ignore this fact is criminal folly on our part. Further, it must not be supposed that the public is disinterested in this matter. It has become health-conscious in spite of, and not because of, us; nevertheless it will seek our help in the future as never before in the attainment of a greater degree of good health for all. The public will play an important part, both in and out of Parliament, in determining the future medical services available to it, and will naturally look to us for guidance, but it will look in vain unless and until we are prepared to take a far wider view than we have done hitherto.

We are in the midst of a world war, and in this country political parties have sunk their party differences to form a coalition the more energetically to pursue the war to a victorious conclusion and to speak to the world with a united voice. Can we not, in our own small way, do the same? Is it Utopian to suggest that a British Medical Corporation should be formed by an amalgamation of all existing representative medical bodies? Is it hopeless to expect such organizations to sink their differences? Is it impossible to speak with a united voice? Are we, as a profession, so far lacking in public spirit, that

prise, and wisdom that we are prepared to witness the unedifying spectacle of the various organizations to which we belong drifting farther and farther apart without raising our voices in protest? Are we to continue on this slippery path to perdition? Will we gain by it, will the public, or will they be the losers as well as ourselves?

I venture to suggest, Sir, that the formation of a British Medical Corporation would be received by Parliament and public alike as an earnest of our intention to put our own house in order. If the suggestion I put forward could be accomplished, we would be in an unassailable position, as a united, authoritative body, to discuss the future medical welfare of the country with the Government. There are difficulties inherent in this suggestion, but are they insoluble? I am not concerned in this letter with actual plans for the future of medicine; I plead for union in the profession under one organization as an absolute necessity.—I am, etc.,

London, S.W.1, Nov. 13.

R. PROSPER LISTON, M.B., Ch.B.

SIR.—There is considerable disquiet among the profession at statements in the Press and in Parliament as to various schemes for altering the terms of both hospital and domiciliary practice without reference to those most intimately concerned with such changes—namely, the medical profession and the public. At a moment when, in the words of the chairman of the B.M.A. Medical Planning Commission, they are "simply exploring the whole field of medical practice" before even attempting to put forward concrete suggestions to the whole profession (which must surely precede consideration by the Government), it would seem necessary to insist that all such unofficial schemes, including those made, for example, by the Nuffield Trust, are not only provisional but indeed premature. It would indeed be fatal if the impression should gain ground that any such suggestions are the considered opinion either of the profession or of the public when neither have been consulted in the matter. That this impression is growing is shown by reports of discussions in Parliament and in the lay press.

One hears from some provincial towns that representatives of the workers have stated that if any attempt is made to regiment them into any State or local government scheme of which they do not approve they will endeavour with the collaboration of the profession to run a voluntary hospital and domiciliary scheme on their own: an interesting commentary on the query of Sir Frederick Menzies as to the essential differences between State and voluntary hospitals as judged by the public.

Another fact which is in danger of being forgotten is that a large number of the younger members of the profession are on Service, and neither the Government nor we who are at home have any right to legislate for them until after the war when they will have returned and can express their views. One hears again that few of them are anxious to see any violent upheaval in the terms of practice, be it hospital or private.

At any rate one would feel reassured to learn that those of our profession in touch with Government circles are making it clear that, while we are interested in any suggestions for post-war medical planning, all schemes adopted and alterations made at the moment must be considered as being purely war measures, which may or may not, as judged by the profession as a whole, remain as part of our peacetime organization.—I am, etc.,

London, N.6, Nov. 13.

W. LEES TEMPLETON.

Medical Education

SIR.—I should like to comment, from the point of view of a schoolmaster who trains about twenty medical students a year, on recent articles on medical education. I fully agree with the view that a physician should have a wide general culture and with the opinion that he is too often without it, but I do not think that "paper changes," such as postponing the study of pre-medical subjects to the age of 17, or taking the First M.B. only from the medical schools, would really attack the problem. The difficulty which the schools have in educating the future medical student is that the universities will mostly accept men to read medicine whom they would reject from most of their honours schools. We cannot refuse to teach these boys, and the result is that the biological sixth, while it usually contains some very good pupils, also has many who are far

below the normal sixth-form level, both intellectually and culturally. Few schools are large enough to separate the two classes, and the teaching of the good boys is dragged down to the level of the others. In this school a partial separation is possible, and most of the better pupils stay for a third year in the sixth; to them we give a good general education; for the others we do the best we can.

I would suggest three remedies, all linked together, of which the universities could put two into practice almost at once. First, a raising of the standard of entrance to the medical schools to approximately that demanded of the honours student. Second, the provision of more scholarships to make up for the loss in numbers caused by the first. Third, the rapid recognition of the schools as the proper place for the pre-medical subjects and the acceptance of a pass in appropriate subjects in the Higher School Certificate in place of the First M.B. The special examination for the latter might in time cease.—I am, etc.,

Manchester Grammar School, Nov. 10.

BRUNSDON YAPP.

Science and World Order

SIR.—I do not think that Mr. O. J. R. Howarth (November 8, p. 671) is justified in saying that the conference of the British Association was the first attempt at international understanding among scientists made in this country. Since the beginning of the war many British scientific bodies, including the Royal Society of Medicine, have turned their activities in this direction, and although less advertised these have been no less successful. I do not deny in my letter that certain foreign representatives had been given a prominent part in the conference, but these were the distinguished Ambassadors of the United States, Russia, and China. This may give a political but hardly a scientific stamp to the conference. Further, the fact that smaller nations were not treated so bountifully has aroused a certain amount of ill feeling which goes against international understanding, for at scientific conferences representatives should not be treated according to the surface area of their countries. I apologize, however, for having said that out of sixty speakers only one dealt with the principal international problem of to-day—European starvation and threat of epidemics—and I accept Mr. Howarth's assertion that "no less" than four speakers referred to the subject. Even so, the proportion is tragically inadequate.

The object of my letter was not criticism of the British Association conference but a constructive proposal for a really international and strictly scientific conference for examination of actual scientific problems. For convocation of this conference the principal British scientific bodies should come to an understanding, for despite its greatness the British Association is not the exclusive representative of British science. Next, contact with the foreign scientific organizations should be made and the plan of the conference should be arranged by British and foreign representatives jointly. An international conference is not built up by a restricted group of scientists belonging to one nation who direct the activities of all the others as they see fit. This is a method of "new order" which is doomed to failure.—I am, etc.,

London, W.1, Nov. 10.

A. P. CAWADIAS.

"Perfect Sight without Glasses"

SIR.—I have noted your annotation "Perfect Sight without Glasses" (September 13, p. 383) and the letter from Dr. J. Parness (p. 389). The work of the late W. H. Bates, M.D., is carried on by his widow, Emily A. Bates, who classifies herself as a "teacher of eye, education, Bates method." Just over seven years ago a friend of mine became so interested in this method that he arranged for Mrs. Bates to visit this city and hold classes. He and scores of his friends, after two weeks' educational course, decided to give up their glasses. I discussed this method with those who were taking the course. They were very enthusiastic, and were quite convinced that they could get along without their glasses. They were able to do so for varying periods, but, in general, only until the enthusiasm subsided. Within a matter of a few months they were all wearing their glasses again, and have continued to do so.—I am, etc.,

Toronto, Oct. 9.

S. J. STREIGHT, M.D.,
Medical Director, Canada Life Assurance Company.

Obituary

WILLIAM FORDYCE, M.D., F.R.C.P.Ed., F.R.C.O.G.

Consulting Gynaecologist, Edinburgh Royal Infirmary

Dr. William Fordyce, who died in retirement at Tillicoultry, Clackmannan, on November 6, was for many years one of the leading obstetricians and gynaecologists in Edinburgh. His death removes the last survivor of a famous group of contemporaries who maintained and enhanced the reputation of the Edinburgh Medical School in that branch of practice and teaching. They included Sir Alexander Simpson (nephew of Sir James Young Simpson), Sir J. Halliday Croom, Dr. Freeland Barbour, Dr. D. Berry Hart, Dr. Milne Murray, Dr. J. W. Ballantyne, Dr. J. Haig Ferguson, Dr. F. W. N. Haultain, and Dr. Lamond Lackie.

Dr. Fordyce was born in 1863 at Liverpool, but both his parents were Fife people, and he was sent to school at Anstruther in Fife and read for an Arts degree at St. Andrews University. He went on to study medicine at Edinburgh University, graduating M.B., C.M. with first-class honours in 1888, and proceeding to the M.D. degree in 1893 after postgraduate work at Leipzig and Berlin. He took the M.R.C.P.Ed. diploma in 1896 and was elected F.R.C.P.Ed. in 1898. Personal friendship with Sir Alexander Simpson drew Fordyce towards midwifery and gynaecology, and he assisted Simpson for several years in the work of his university chair at Edinburgh. Later he was appointed lecturer in the Extra-Mural School of the Royal Colleges and was elected to the visiting staff of the Royal Maternity and Simpson Memorial Hospital as assistant obstetric physician; some time afterwards he was appointed to the obstetrical and gynaecological staff of the Edinburgh Royal Infirmary. He was also for many years gynaecologist to the Leith Hospital and to the Hospital for Women in Archibald Place.

Dr. Fordyce was noted for his diagnostic powers and operative skill. He was a regular attendant at meetings of the Edinburgh Obstetrical Society and often contributed to its proceedings; he became President of that society in 1919 and devoted his presidential address to a historical survey of the development of gynaecology. He had been a member of the British Medical Association for forty-five years, and at the Annual Meeting in Edinburgh in 1927 was vice-president of the Section of Obstetrics and Gynaecology. In 1929 he was one of the Foundation Fellows of the Royal College of Obstetricians and Gynaecologists. He retired from active practice about ten years ago.

Outside his profession Dr. Fordyce had many interests. He was a keen fisherman and golfer, and enjoyed curling. His turn for the writing of light verse was well known to a wide circle of friends, and he often sang or recited his own compositions at medical and other dinners. Of these he was persuaded to publish privately a selection in a small volume entitled *The Old Sport and Other Verses*. He had been for many years a member of the Scottish Arts Club.

H. MORELAND MCCREA, O.B.E., M.D.

Dr. Hugh Moreland McCrea, who died on November 8, was born in Belfast in 1877 and came of medical stock; both his father, John McCrea, and his grandfather, Prof. Dill, were well-known physicians in Belfast. He was educated at the Royal Academical Institute, Belfast, and left as head of the school to enter Queen's University as science scholar. He was naturally attracted to the medical side of the university, and in a distinguished career obtained in succession the only two medical scholarships then existing in Belfast University.

After two years' residence in hospital he came to England, and for a few years practised at Wargrave, where he soon made a reputation as a consultant physician. In 1907 his practice as a

consultant had so far increased that he decided to come to London. He married the daughter of Charles Hadden of the Chinese Customs. In 1915 he was appointed physician to the City of London Military Hospital, and there acted as senior physician for five years. He was anxious to serve abroad, and in 1916 was actually appointed O.C. of a hospital fitted out for Salonika, but two days before the unit sailed a medical board refused to pass him as fit for duty over-seas, to his great disappointment. At the end of the war, and while still carrying out his duties at the military hospital, he was appointed chairman of the second final Medical Appeal Board of England and Wales. In addition to this he took a large share in organizing the Emergency Medical Corps under the auspices of the Royal Society of Medicine. The corps was a very active body, and actually answered no fewer than 68 air-raid calls. He was awarded the O.B.E. for his distinguished service.

But Dr. McCrea's most enduring contribution to medicine in London is the London Clinic, which owed its origin to his inspiration and its realization to his energy. He was chairman of the Medical Advisory Board, and for years it was the chief centre of his ambition, and only those who worked with him can realize the almost insuperable difficulties with which he had to contend.

Those who worked with Dr. McCrea will feel his loss as a physician of wide human sympathies, whom they could always call upon in cases of difficulty and whom they were sure would spare no exertion to help his patient. But they will miss him most as a real colleague and a very dear friend.

H. S. SOUTAR.

Sir G. LENTHAL CHEATLE writes:

The death of my friend Dr. Hugh Moreland McCrea terminates the activities of an alert, wise, and busy mind. On the public side of his life he founded the present London Clinic and Nursing Home. Its chief objects were to supply private patients with all the privileges and advantages of a first-class public hospital. Its reach for some insurmountable reason was premature and beyond the grasp of those who supported him; but it did result in building the only institution of its kind in this country that contains within its walls a pathological laboratory and x-ray department, each separate and under the control of men of the highest reputation. The ideals that gave rise to its birth would have supplied all the requirements in the treatment of private patients, and may yet be realized. In the conduct of his private practice Dr. McCrea achieved these ambitions. At his own expense he established a laboratory and an assistant for the proper examination, control, and treatment of his patients. His kindness and competence will be for ever missed by those who were fortunate enough to come under his skilful care. Dr. McCrea's life was an example to all those who practise medicine.

Mr. VICTOR BONNEY writes:

By the death of Hugh Moreland McCrea a very remarkable man is lost to our profession. The qualities in the aggregate required to make a great clinical physician are much more rare than those needed to make a great surgeon, for the problems presented to the latter are solvable chiefly by touch, sight, and personal dexterity, whereas those with which the physician has to cope require not only the piecing together in order of importance a number of data obtained from various sources but the correct deduction from the whole assemblage. The power of doing this varies with individuals, but from time to time men appear who, possessing a faculty for retrieving and marshalling in surprising context impressions latent in sub-consciousness, have it in remarkable degree. The term *clair* is commonly used to describe this faculty, and McCrea was one of these gifted persons. To the gift was added an insatiable zest for professional knowledge which was continually added to by acute observation and voluminous reading. The result was a many-sided physician without one weak facet, so that whatever the nature of the case he brought to it the ability of an expert in that particular malady. His outstanding professional qualities became so widely recognized that he may justly be termed the consultant's physician, so many of them and so he his abilities, for he threw his whole heart into every case, great

or small, to which he was called, and a multitude is in his debt. His passing enhances a regret, often felt before, that he was never on the staff of a teaching hospital, where the high ideals and deep mine of clinical lore of which he stood possessed could have been passed on to the younger men coming after him.

ROSA BALE, L.R.C.P.&S.E.D.

Dr. Rosa Bale died at Barnstaple on November 3, after a brief illness. She had her professional training at the London School of Medicine for Women and obtained the Scottish triple qualification in 1892. She was the first woman to start in general practice in the West of England, and up to last March still did a little work for old patients and friends at her home in Plymouth.

For nine years Dr. Bale ploughed a lonely furrow and faced much opposition and abuse. But she lived to prove that her job was a woman's job, and a long list of her patients and friends proves that she did it well. She was a woman of strong religious principles: week by week she held a women's Bible class and helped many a weary woman to hold on to the Christian faith. Strong for temperance, she always took her place among the band of workers in our midst who pleaded the cause of total abstinence; but she prescribed alcohol when needed. When the Passive Resistance movement was strong against the levying of the education rate, because religious instruction was not given in the council schools, she year by year took her place in the court and a piece of her furniture was sold to pay the rates. She was a Suffragist, and although non-militant she did her bit to win votes for women.

Her home was seriously damaged by enemy action. Then began the first signs of illness of which she was to die. Up to that time she had refused to seek safety because, in her own words, "the Plymouth Education Authority have not evacuated the school children: I cannot leave Plymouth and those for whom I work, and prove myself a coward." Since March she had lived with her brother and sister at Barnstaple, but she grieved sadly for her Plymouth friends and home. Many will remember her association with the Plymouth Education Committee, the Council of Social Service, the Mental Deficiency Committee, the Salvation Army, and temperance work. She did much to improve the midwifery service both as a teacher at Three Towns Nursing Association and as a practitioner.

Dr. Bale was a member of the British Medical Association for forty years and of the Medical Women's Federation (ex-president S.W. Association); she was also an honorary member of the oldest medical society in Plymouth, being the second woman doctor allowed to join it. Her associations with her medical colleagues were always of the happiest, and she inspired the younger medical women with her wise advice and help. When she had done thirty-three years' practice at Plymouth she was presented with an illuminated address of thanks by her women medical colleagues for her wise pioneering and guidance. Since her start in practice forty-three years ago some twenty to thirty medical women (and more in other parts of the West of England) have followed the path which she pioneered, so that to-day in Plymouth medical women are in practice in surgery, medicine, pathology, radiology, and public health; a candle light has become a flaming torch. Beloved by all, setting a noble example, always ready to help the needy and poor, Rosa Bale has passed from our midst and we mourn a great woman.

MABEL L. RAMSAY.

We announce with much regret that Dr. JOHN CARSON LOUGHRIDGE died on October 5 at his residence, Whitewell, Co. Antrim. He was educated at Queen's College, Galway, and Queen's University, Belfast, and took the Scottish triple qualification in 1892. Dr. Loughridge was a hard-working member of the British Medical Association, to which he had belonged for thirty-four years. He was chairman of the Belfast Division in 1924-5; president of the Ulster Branch and a member of the Central War Emergency Committee in 1929-30; member of the Central Council from 1931 to 1939; member of the Irish Committee from 1932 to 1936; and representative at seven

Annual Representative Meetings from 1925 to 1931. Dr. Loughridge had been dispensary medical officer of Whitewell area for many years. Apart from being a local magistrate he was associated with many charitable organizations in his district. Some years ago he was bereaved of his only son, Dr. Jack Loughridge, in a motor accident near his home at Templepatrick, Co. Antrim. He is survived by Mrs. Loughridge, to whom the sympathy of all his colleagues is extended.

Dr. WILLIAM PARKER died on November 4 at Farndon, Cheshire, at the age of 75. Born at Rossett, Denbighshire, he graduated M.B., C.M. at Edinburgh in 1887, at the age of 21, and in the same year started practice at Holt, a few years later moving across the Dee to reside at Farndon. He had a very wide and extensive country practice among people who came to recognize and value his ability, kindness, and great consideration for others. He lived a life of altruism, the financial side of practice being quite a secondary one to him. The affection his patients had for him was deep and abiding, and was manifested in many ways in words and in deeds. When, due to failing health, some five years ago he retired, more than a thousand, rich and poor, subscribed to a testimonial of their regard for him, which included a cheque for about £400. His special hobby was farming and stock-raising, and he much enjoyed discussions with his many farmer friends of the merits of certain breeds of cattle, of which he had practical and erudite knowledge. My friendship (writes W. H. L.) with him dates back to our student days, and as the years passed it became closer and dearer. It could be truly said of him that he was one that loved his fellow men. A true man, of whom all who knew him thought and spoke well and regarded with affection and esteem. He is survived by his wife and daughter.

Although Dr. JAMES KINGSTON BARTON retired from practice a good many years ago, there must be still a very large number of colleagues and patients who will mourn his death, which occurred recently at Wimbledon at the age of 87. From St. Bartholomew's Hospital, where he was Bentley Scholar in 1874, he qualified M.R.C.S., L.R.C.P. in 1875, and was ophthalmic house-surgeon there; he became M.R.C.P. in 1894. For a great number of years he practised in South Kensington, close to Gloucester Road Station, where he had a very extensive clientele indeed. He was the founder and a lifelong supporter of the Kensington Medical Reading Society, which in the end supplanted the much older similar social medical club known as the Brompton M.R.S. Not only at the meetings of this friendly collection of colleagues but in many other ways as well he could be relied on to help and encourage junior practitioners with freely dispensed wisdom and advice. As the years went on he became the admitted doyen of South Kensington practitioners, affectionately looked up to by patients and doctors alike. As far back as 1900 he published *Records from General Practice*. His strong lean face was often lit up by the twinkle of a kindly humour, and his whole outlook was one of humane and upright urbanity, with a pleasing self-confidence in his own really great professional ability. At a time when the black tailed coat and the stiff white collar were still thought indispensable for a Kensington doctor, Barton adopted flannel shirts and tweed suits; yet never gave the slightest impression of being unsuitably or untidily dressed. He was also one of the first in his district to give up his horsed carriage and adopt the "new-fangled motor," which he often drove himself. Nor did he rely on a garage service to diagnose and treat the ailments of his car: the writer vividly remembers seeing him in the street more than thirty years ago with smears of black oil on his face as he emerged from investigating some disorder in the interior of his engine. A very exceptional doctor and a very exceptional gentleman.

E. J. B. Miller (*Med. J. Australia*, 1941, 1, 614) records the case of a boy aged 14 who in convalescence from varicella developed iridocyclitis of the right eye and paralysis of the sphincter pupillae. When seen eight months later the pupil was still dilated, but the fundi were healthy and there was good binocular vision.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Appointments Committee of the Faculty of Biology "B" will shortly proceed to appoint a University Demonstrator in Pharmacology. Particulars of this post, which will be governed by the Statutes and Ordinances of the University, may be had from the secretary of the Appointments Committee, Mr. H. E. Tunnicliffe, Department of Physiology, Cambridge, to whom application should be addressed before December 9.

At a Congregation to be held to-day (Friday, November 21) a Grace is being submitted; on the recommendation of the General Board, that the Final M.B. Examination begin in the present term on Monday, December 8, a day earlier than is prescribed by Ordinance. The number of candidates for this examination is abnormally high, and it is not possible to conduct the examination in the normal manner.

During October the titles of the degrees of M.B., B.Chir. were conferred by diploma on E. H. M. Gillieson and R. M. Stevenson of Newnham College.

UNIVERSITY OF LONDON

WESTMINSTER HOSPITAL MEDICAL SCHOOL

An entrance scholarship examination in anatomy and physiology will be held on Thursday and Friday, December 11 and 12. Two scholarships will be awarded, each to the value of £75. Further particulars can be obtained from the Secretary, Westminster Hospital Medical School, Horseferry Road, S.W.1.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

At a meeting of the Council of the Royal College of Surgeons of England, held on November 13, with Sir Alfred Webb-Johnson, President, in the chair, Messrs. R. Milne, R. Davies-Colley, G. T. Mullally, V. Zachary Cope, C. E. Shattock, and E. W. Riches were re-elected members of the Court of Examiners for the year beginning December 11, 1941.

It was proposed to hold a Buckston Browne lunch on Thursday, February 12, 1942.

Diplomas

Diplomas of Membership were granted to the 159 candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of November 8 (p. 675).

Diplomas in Public Health were granted, jointly with the Royal College of Physicians of London, to L. C. Lodha, L. G. Norman, and M. A. G. Ward.

SOCIETY OF APOTHECARIES OF LONDON

The following candidates have passed in the subjects indicated:

SURGERY.—T. L. Benson, H. V. T. Payne, G. M. Pearson, R. L. Skea, J. S. Taylor, S. S. Zoha.

MEDICINE, PATHOLOGY, AND FORENSIC MEDICINE.—C. R. Deuchar, J. S. Taylor, H. A. Worthy.

MIDWIFERY.—M. Fishman, M. C. Hannon, W. J. Lewis, Pak So, W. C. Salter.

The diploma of the Society has been granted to G. M. Pearson, J. S. Taylor, H. A. Worthy, and S. S. Zoha.

The Services

MENTION IN DISPATCHES

Surgeon Lieut. Patrick O'Brien, R.N. (H.M.S. *Defender*), has been mentioned in dispatches for gallantry and distinguished services in operations in Greek waters.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL ARMY MEDICAL CORPS

The name of Major MARTIN MCAULEY MORROW is included as "Died" in an Army Council Casualty List published on November 8. He was educated at Queen's University, Belfast, where he graduated M.B., B.Ch., B.A.O. in 1936. He entered the R.A.M.C. as lieutenant in 1938, became captain in 1939, and was recently promoted to major. He had been a member of the British Medical Association since 1937.

Prisoners of War

Major Arnold Gourevitch
War Substantive Captain John Hunter Annan.
War Substantive Captain Lachlan Maclean.

Medical Notes in Parliament

Health in the Debate on the Address

A new Session of Parliament was opened by the King in person on November 12. The Speech from the Throne spoke of the strengthened resolution of the British Nations to prosecute the war to final victory, and announced that Parliament would be asked to make further financial provision for its conduct. A promise was given that the Government would continue to take all practical steps to sustain the health and well-being of the people under the stress of war.

Speaking in the House of Lords on November 12 during the debate on the Address, Lord ADDISON praised the Speech's emphatic declaration about the health of the people, and welcomed the steps which were being taken to provide more milk for school children. He thought the war provided opportunities for developments in improved nutrition which peace hitherto had not made possible. He hoped for further advances and said the Labour Peers would, at an early date, ask the House of Lords to consider this subject. Lord MOYNE, in reply to the debate, said the Government's Colonial policy must press on with the improvement of health facilities. At home, despite the suffering and waste of war, they had improved the social services. The remarkable record of national health was largely due to the food policy of Lord Woolton, which had brought nutrition on the best scientific advice within the reach of many who previously suffered from some deficiency. To-day had brought the announcement that children up to the age of 2 were to get free supplies of vitamins.

Mr. CHURCHILL, speaking in the House of Commons on November 12, said an Education (Scotland) Bill was required so that full effect might be given in Scotland to the Government's scheme for nutrition of children by maintaining a high standard among school children and by expanding as rapidly as possible the provision of meals and milk in schools. He went on to say that the dietary of the people, though curtailed and less varied, was sufficient for physical health. He hoped the Government would be able to give a larger share of available supplies of meat to the workers who needed it most. This would be done by rapid expansion of canteens. The Minister of Food had been able to make, during the winter months, minor relaxations in his restrictions.

In fulfilment of Mr. Churchill's promise of November 12, the Education (Scotland) Bill was introduced in the House of Commons on November 13 by Mr. T. JOHNSTON. It proposes to amend the law regarding the provision by education authorities of food and clothing to school children.

Committee on Nurses' Salaries.—On November 11 Mr. ERNEST BROWN told Sir Joseph Lamb that the present terms of reference to the committee under the chairmanship of Lord Ruchilife extended only to the salaries and emoluments of nurses who were either State-registered or in training with a view to State registration, including any members of the staff of public assistance institutions covered by this definition.

Purchase Tax and Diagnostic Reagents.—Mr. PRICE asked the Secretary to the Treasury whether it was intended that all biological products used for medical and veterinary purposes should be exempted from purchase tax; why such items as tuberculin, John's, and B. coli antiserum solely used for veterinary purposes were not referred to in Statutory Rules and Orders, No. 1390, 1941; and if he could put this matter right at an early opportunity. Captain CROOKSHANK said that exemption was intentionally confined to certain medicines and drugs of a specially costly character considered essential for the treatment of disease, and in the case of veterinary preparations for the treatment of serious diseases of livestock of economic importance. Diagnostic reagents were not regarded as taxable medicines, and it was accordingly unnecessary to exempt substances such as those mentioned in the second part of the question which were prepared for such use.

The Vienna Health Office has recently asked for the most rapid institution of measures to obtain serum from convalescent cases of poliomyelitis. All persons who have had the disease within the last six years are invited to offer their blood.

No. 44

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 1.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Stillbirths	157	17	35	—	—	219	24	31	—	—
Rate per 1,000 total births (including stillborn)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

A general decline in the incidence of infectious diseases in England and Wales occurred during the week, the only exception being cerebrospinal fever with an increase of 14 cases compared with the preceding week. The largest outbreaks of dysentery during the week were in Cornwall (Bodmin M.B. 9), Staffordshire (Lichfield R.D. 9), Lancashire (Blackburn R.D. 8).

The notifications of infectious diseases in Scotland also showed a decline, although there were 18 cases of diphtheria in excess of the preceding week. The largest decline was in respect of dysentery, notifications of which fell from 95 to 51.

Paratyphoid and Typhoid Fevers

A further decline was recorded in the incidence of these diseases in England and Wales during the week. Local centres of infection, which have been a feature of the returns during recent months, are tending to disappear, and the total is now formed of isolated and widely distributed cases. The 35 cases of paratyphoid were in fifteen counties, the largest returns being those of Warwickshire 7 and Hertfordshire 6. The 20 cases of typhoid were contributed by sixteen counties.

Cerebrospinal Fever

An increase of 14 cases over the preceding week was recorded in England and Wales. Almost half the notifications occurred in four counties—namely, Durham 9, Lancashire 17, Warwickshire 8, and Yorkshire, West Riding, 8.

The incidence of this disease has shown, of all the infectious diseases, the greatest increase during the war. The following table makes a comparison of the trend, in four-week periods, between this year, 1940, and the immediate pre-war years:

Week	No. of cases notified		Av. of 1937-9	Cases as a percentage of the average of 1937-9	
	1941	1940		1941	1940
1-4	1,092	488	137	797	356
5-8	1,483	1,847	140	1,059	1,319
9-12	1,437	2,237	146	984	1,532
13-16	1,256	1,749	131	959	1,335
17-20	1,110	1,401	120	925	1,167
21-24	992	1,001	98	1,012	1,021
25-28	777	830	91	854	912
29-32	604	703	75	805	804
33-36	463	470	64	723	734
37-40	439	471	64	688	735
41-44	403	535	70	576	764

The epidemic of 1940, which began in the first weeks of the year and reached a maximum of 617 cases in the ninth week, failed to subside to the pre-war endemic level; as a result the notifications in the first weeks of this year were higher than in the preceding year. The rate of increase in the first weeks of this year was below that of last year, and despite the higher initial level the maximum weekly notification was only 430, occurring in the eighth week. During the weeks following the maximum the rate of decline was less this year than last. The fall in the number of cases from weeks 9-12 to weeks 29-32 was 73% in 1940 and 58% in 1941. The decline has persisted for a longer period this year than in 1940, when the trend during the last three of the four-weekly periods tabled was similar to the pre-war years, although at a considerably higher level.

Quarterly Return for England and Wales

The returns for the second quarter of 1941, published by the Registrar-General, show that the births and deaths have deviated much from the recent trends. A death rate of 13.5 per thousand was recorded, compared with 11.6 for the second quarter of 1940 and 11.7 for the average of the five years before 1940. The birth rate was 14.2 per thousand, compared with 16.2 in the second quarter of 1940 and 15.8 of the five preceding years. Infant mortality was 59 per 1,000 live births, 6 above the average of the ten preceding second quarters. Stillbirths formed 3.6% of all births. The natural increase (excess of births over deaths) was only 7,355, as compared with 46,980, 43,777, and 44,991 for second quarters of the three years 1940-38.

Returns for the Week Ending November 8

Notifications of infectious diseases during the week in England and Wales included scarlet fever 1,366, whooping-cough 2,029, diphtheria 1,069, measles 747, cerebrospinal fever 113, poliomyelitis 33, dysentery 148, paratyphoid 31, typhoid 12. Twenty deaths were due to influenza.

Medical News

Group Captain C. P. Symonds will deliver a lecture on "Meningitis" at the Weston Hotel, Bath, on Thursday, November 27, at 5.30 p.m. All Service medical officers and civilian practitioners will be welcome.

The meeting of the Section of Neurology of the Royal Society of Medicine, which was to have taken place at Chase Farm Hospital, Enfield, on November 15, will be held on Saturday, November 22, instead.

The next quarterly meeting of the Royal Medico-Psychological Association will be held at 11, Chandos Street, W., on Wednesday, November 26, at 2.15 p.m., under the presidency of Dr. Thomas C. Graves, F.R.C.S. Dr. E. L. Hutton will read a paper on "The Investigation of Personality in Patients treated by Prefrontal Leucotomy."

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, November 27, at 4 p.m., when Dr. H. Neville Stafford (coroner, County of London, Western District) will read a paper on "The Coroner and Civilian War Deaths."

The annual meeting of the Medical Benevolent Society for the East and North Ridings of Yorkshire was held recently in the rooms of the York Medical Society, Stonegate, York. After routine business was completed the following officers were elected for the ensuing year: President, Dr. Thornley of Beverley; President-Elect, Dr. M. Jacobs of Hull; Vice-President, Dr. Longbotham of Middlesbrough; Honorary Treasurer, Dr. Mackay of Hull; Honorary Secretary, Dr. Kelly of York. An application for aid was received on behalf of a disabled member, and it was decided to make a grant towards the education expenses of his son, who will be selected in April, 1942, for a university course. It was also decided to invest the credit balance for the past year in 3% Defence Bonds.

On November 13 at Liverpool Assizes Mr. Justice Croom-Johnson passed sentence of four years' penal servitude on John Knox Thompson, M.B., B.S., R.U.I., of Princes Road, Liverpool, and ordered him to pay the costs of the prosecution. Dr. Thompson, who is 61 years of age, had been found guilty on ten counts under Defence Regulations of having issued untrue medical certificates to members of H.M. Forces, and on a further count of having attempted to obtain £1 14s. 6d. from the War Department by false pretences. The judge, in his stern comment when passing sentence, said he had thought carefully over the case to see whether he could find the smallest excuse or extenuating circumstance for what the accused had done, but he found none; Dr. Thompson had brought scandal and disgrace on a noble profession.

The Medical Research Council has decided to print the monthly bulletins of the Emergency Public Health Laboratory Service, so that copies may be distributed more widely than has hitherto been practicable. The first to be printed is the November issue, and deals, among other matters, with paratyphoid in the Liverpool area, an outbreak of food-poisoning in Oxford, and a further one in Romford.

In a circular (2517) issued by the Ministry of Health on November 14, attention is directed to a new regulation, relating to scabies, which has been added by Order in Council to the Defence (General) Regulations, 1939. The regulation enables the Minister to make an Order providing for the inspection of premises in which verminous persons are or have been accommodated, for the examination and treatment of any other verminous person in such premises, and for any necessary cleansing or destruction of articles on such premises—all this if the Minister is satisfied that "scabies or any other disease associated with verminous conditions is so prevalent as to prejudice the efficient prosecution of the war, or the maintenance of supplies and services essential to the life of the community." The Scabies Order has now been made, and powers are given to local authorities to take the necessary steps to bring under control this widespread infestation of the public.

On November 12 Dr. Astley V. Clarke was nominated as a sheriff for the County of Rutland.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the Journal and subscriptions should be addressed to the Secretary.

QUERIES AND ANSWERS

Intermittent Polyuria

Dr. G. BAYNTON FORGE (Salisbury) writes in reply to G. A. G. S. (April 26, p. 658): In similar cases I have obtained excellent results from eulavine (neutral acriflavine) in 1/2-grain doses t.d.s. Very often two tablets will secure the desired result in one day. The condition seems to be due to an increase in the number of colon bacilli, and the acriflavine acts promptly. I usually give 100 tablets, 1/2 grain, enteric-coated, from British Drug House.

LETTERS, NOTES, ETC.

Blood Grouping in the Forces

Dr. W. LEES TEMPLETON (Highgate, N.6) writes: In a recently published book, *Under the Iron Heel*, by an American who lived in Belgium up to 1940, the author comments on the thoroughness of the German preparations, and mentions as one example the fact that on each soldier's identity tag is placed, in addition to the usual name and number, his blood group, so that even on the field it is possible for any man, even a high staff officer, to be stopped and, if it is required, to be compelled if of a suitable group to give his blood. It may be, of course, that similar precautions are taken in our own Army, but it would seem that it is something worth copying not only in the Forces but among the civilian population. That it would entail a lot of work is undoubtedly, but one feels that it could be undertaken—for example, by members of the E.M.S. staffs standing by during quiet periods.

Anti-tobacco Campaign in Germany

An article by Prof. Hans Reiter, president of the Reich Health Office, on the evils of tobacco-smoking appears in the *Reichs-Gesundheitsblatt* of July 2, 1941. The article is based on the investigations into the dangers of tobacco undertaken at a meeting in Weimar last spring, where it was stated that it was the right and duty of the State and party to combat the evil of tobacco-smoking by every possible means. The individual is asked to make sacrifices for the community. Formerly the "property condition" of a State was the standard of its wealth. Under the Führer the wealth of a country consists in its biological possibilities of development, and the condition of a nation's health is the measure of its cultural and material value. An intensive campaign of organized propaganda against the consumption of tobacco, financed by the State, is to be undertaken in the Press, theatres, cinemas, and all places of public assembly.

Treatment of Scabies

Dr. E. DRYBROUGH-SMITH (Sutton Coldfield) writes: The following is a simple and effectual way of treating scabies in the home. The patient is directed to sponge the body with warm water and soap (a tub of hot water is all that is required); the skin is then rapidly rubbed over with a towel, and before it is thoroughly dry it is sprinkled over with flowers of sulphur (sublimed sulphur), avoiding the eyes. Some of the sulphur is also sprinkled between the bed sheets. In the case of adults this is performed on three consecutive nights, in the case of children on two in order to avoid sulphur rash. On the day following the completion of treatment the patient should put on clean underclothes and clean sheets which should be put on the bed; no more sulphur should be used. As regards infected clothes and bedding, I understand that in most large towns the health departments will collect these, sterilize them, and return them on the same day, free of cost. Where that service is not available linen and cotton underwear and bedding should be boiled, and flannels and blankets should be steeped in a solution of lysol in water of a correct strength and then hung out in the open to dry. The advantages of this method are: it is quick, it is undertaken and the patient easily understands it; many infections are avoided and valuable fats are saved; it is cheap (linen and hospitals should welcome that); it is easily carried out in a country cottage or in the town-worker's home.

COMBINED ACTIVE AND PASSIVE IMMUNIZATION AGAINST DIPHTHERIA

II. CONTROL OF EPIDEMICS IN THE FIELD*

BY

F. FULTON, M.A., B.M., B.Ch.

JOAN TAYLOR, M.B., B.S., B.Sc., D.P.H.

A. Q. WELLS, D.M.

AND

G. S. WILSON, M.D., F.R.C.P., D.P.H.

(From the Emergency Public Health Laboratory, School of Pathology, Oxford)

In the previous paper (p. 717) evidence was brought to show that by means of combined active and passive immunization a degree of active immunity can be produced which, though slower in its development, is ultimately not greatly inferior to that resulting from active immunization alone.

Attention was drawn to the difficulty in practice of protecting children against diphtheria during the intermediate phase of relative susceptibility which, according to Gundel and König's (1938) experiments on guinea-pigs, probably occurs between the waning of passive immunity due to the injection of antitoxic serum and the development of active immunity due to inoculation with diphtheria prophylactic. Information on the length and degree of this intermediate phase of relative susceptibility cannot be obtained in human beings by the direct experimental method, but the observations of Gierthmühlen and Voges (1939) on children during an actual epidemic of diphtheria suggest that with doses of 0.3 to 0.5 c.cm. of A.P.T. and 1,000 units of antitoxin it is at its maximum between about three and six weeks after the first injection of A.P.T. and serum, and that it is considerably less in degree than the susceptibility of uninoculated children.

Though this information was not available to us when we were conducting the observations about to be described, we were fully aware of the possible occurrence and danger of such an intermediate phase of relative susceptibility. It seemed to us, therefore, that, if an outbreak of diphtheria was to be brought under immediate and complete control, the only satisfactory way to prevent fresh cases from developing during the relatively susceptible phase was by protecting the children so far as possible from further risk of exposure to infection. This we proposed to do by detecting all carriers in the community and segregating them until the remaining children had acquired an adequate degree of active immunity.

Method of Controlling an Outbreak of Diphtheria

The method we adopted when it was evident that an outbreak of diphtheria in a school had begun was as follows:

1. Separate swabs were taken from the nose and throat of all children and teachers in non-residential schools and of the complete staff in residential schools. These were streaked on to a modified Horgan and Marshall tellurite blood agar, and

* Part I, "Studies of Antitoxin Response in Normal Students," appeared last week.

diphtheria bacilli that developed were typed in the usual way. All strains of *mitis* and of *intermedius* type were uniformly tested for virulence to guinea-pigs, and a proportion of the strains of *gravis* type.

2. At the same visit all children were inoculated simultaneously into the left upper arm with 0.1 c.cm. of Burroughs Wellcome's alum-precipitated toxoid (A.P.T.) and into the right upper arm with 350 to 500 units of refined diphtheria antitoxin globulin (Pope, 1938, 1939) contained in about 0.1 c.cm. of serum. All injections were given into the deep subcutaneous tissue. The use of refined serum greatly lowers the incidence of serum rashes (Hutchison, 1939; Parish, personal communication, 1940).

3. All carriers were isolated or segregated as soon as the results of the swabs were known.

4. Four weeks later all children, including the carriers, were given 0.3 c.cm. of A.P.T. into the right upper arm.

5. All carriers were allowed to return to school two weeks after the second inoculation with A.P.T., but, though permitted to mix freely with the other boys and girls, they were forbidden, in residential schools, to participate in games with visiting teams. Any carrier who gave three consecutive negative swabs on tellurite blood agar before the end of the six-weeks period of segregation was allowed to return to school at once.

This general technique was adopted in seven outbreaks of diphtheria for which our help was sought. In the first three outbreaks it was modified by Schick-testing and swabbing the children at the first visit in accordance with the recommendation of Okell, Eagleton, and O'Brien (1924), and giving combined active and passive immunization three days later to the positive reactors. A single dose only of 0.3 c.cm. of A.P.T. was given to the negative reactors to serve as a stimulus to their antibody-producing mechanism. Preliminary Schick-testing was subsequently abandoned owing to the high proportion—75 to 90%—of susceptible children usually met with in the non-residential type of school population with which we later had to deal and to the waste of time involved. Not only did it necessitate an extra visit for the immunizing staff, but it meant the loss of three days in protecting the children at a time when they were most likely to develop infection. Another modification concerned the typing of the diphtheria bacilli, which was not undertaken as a routine in the early outbreaks investigated.

Results

The following is a brief description of our observations on the individual schools:

Royal Merchant Navy School.—This is a boarding school for about 200 boys and 100 girls. Diphtheria broke out, mostly

of the nasal type, in October, 1939. By the beginning of December, 1939, when this laboratory was consulted, some 20 cases had occurred. All the children, as well as the teaching and domestic staff, were swabbed. Schick tests were carried out on the children, but not on the staff. Three days later the Schick tests were read: 58.4% of the children proved positive. With one exception all the Schick-positive children, the children in the hospital and sick bay, the domestic staff, and many of the teaching staff were given 400 units of antitoxin and 0.1 c.cm. of A.P.T. The second dose of 0.3 c.cm. of A.P.T. was given four weeks later. The swabs revealed 21 carriers of virulent diphtheria bacilli; 12 of these were carrying in the throat, 6 in the nose, and 3 in both throat and nose. These carriers were isolated for six weeks—that is, two weeks after the second injection of 0.3 c.cm. of A.P.T. Eight weeks after the second injection the children were re-Schicked. A conversion rate of 97% was recorded. The 3% of children who still reacted positively were given a third dose of 0.3 c.cm. of A.P.T. Two cases of diphtheria occurred after the first visit of the laboratory staff. One was in a boy who was removed from school by his parents without being immunized. The other, which was extremely mild, occurred in March, 1940, in a girl who had entered school in January with a history of having just received one immunizing injection of an undisclosed antigen at home. She was given 0.3 c.cm. of A.P.T. at school six days after her first injection. The interval between the two doses was presumably too short to enable an adequate degree of immunity to develop.

Turner's Court Training Colony.—This is a training colony for males between the ages of 14 and 24, and contains some 300 pupils. At the time of the first visit of the laboratory staff in December, 1939, at least 6 cases of diphtheria had recently occurred, one of which had proved fatal. Owing to the age of the boys, the whole colony was Schick-tested; 36% of the total were Schick-positive. The positive reactors were given 350 units of antitoxin and 0.1 c.cm. of A.P.T., followed four weeks later by 0.3 c.cm. of A.P.T. Nose and throat swabs which were taken at the first visit from all the boys revealed the presence of 11 carriers of virulent diphtheria bacilli. Six of these were carrying in the throat and 5 in the nose. The carriers were isolated for six weeks, but were not treated in any way. The pupils were re-Schicked eight weeks after the second injection. The conversion rate was 97.7%. The two boys who still reacted positively were given a third dose of 0.3 c.cm. of A.P.T. Two cases of diphtheria occurred subsequent to our first visit. One was, a few days after Schick-testing, in a boy whose immunizing record was defective; the other was in March, 1940, in a new boy who had entered the colony in the meantime without being immunized.

Chadlington and Spelsbury.—In these adjacent villages in Oxfordshire 22 cases of diphtheria were reported between January and November, 1939. All except three were in school children. Twenty of the cases had occurred at Chadlington, where the school population was about 120, and two at Spelsbury, where the school population was about 50. Closure of the school at Chadlington on three occasions for a considerable time had failed to prevent the occurrence of further cases. In November, when this laboratory was called in, Schick-testing was carried out on all the available school children, and nose and throat swabs were taken; 76% of the children proved to be Schick-positive. These children, together with those who had not been available for testing, were given 350 units of antitoxin and 0.1 c.cm. of A.P.T. The parents of 13 children refused immunization; these children were therefore excluded from school, together with 3 who were found to be carrying virulent diphtheria bacilli—2 in the throat and 1 in the nose. The school was reopened as soon as the carriers had been isolated. A second dose of 0.3 c.cm. of A.P.T. was given one month later to those children who had received a first dose. No cases of diphtheria occurred in either village after the beginning of immunization. Of the children who had been immunized 87 were re-Schicked ten weeks after the second dose of A.P.T., and a conversion rate of 96.5% was recorded. The two positive reactors were given a third dose of 0.5 c.cm. of A.P.T.

Chippenham.—In a day school containing over 400 children 7 cases of diphtheria occurred within a single week in the middle of October, 1940. The school was visited at once.

Nose and throat swabs were taken from 360 of the children, all of whom were given 500 units of antitoxin and 0.1 c.cm. of A.P.T. No fewer than 27 carriers of virulent intermediate type of diphtheria bacilli were found—22 nasal, 4 throat, and 1 nose and throat. These were excluded from school for six weeks. Four weeks after the first visit the children were given a second immunizing dose of 0.3 c.cm. of A.P.T. Only one case of diphtheria occurred subsequent to our first visit, and that was in a child who had left the school without being immunized.

Lyneham and Tockenham.—In these two small adjacent villages in Wiltshire 9 cases of diphtheria, 2 of which were fatal, occurred between October and December, 1940. The school population numbered about 100. In the beginning of January, 1941, the children were given 500 units of antitoxin and 0.1 c.cm. of A.P.T. At the same visit nose and throat swabs were taken. Six carriers of the virulent gravis type of diphtheria bacilli were found; 3 were nasal, 2 were throat, and 1 was both nose and throat. These children were excluded from school for six weeks. Four weeks after the first immunizing dose the children were given a second dose of 0.3 c.cm. of A.P.T. No further cases of diphtheria occurred.

Leafeld.—Two cases of diphtheria occurred in this Oxfordshire village. One was in an evacuee school child in August, 1940; the other was in a local child in November, 1940. Swabs were taken on November 11 and 15 from 170 children and staff, with the result that 22 carriers of diphtheria bacilli were found, all of the virulent mitis type; 4 were nose, 13 throat, and 5 nose and throat. Though cases of clinical diphtheria had been few, it was decided, owing to this high carrier rate, to give combined active and passive immunization to the children. This was done on November 20, when 0.1 c.cm. of A.P.T. and 500 units of antitoxin were injected. Since hospital beds for the isolation of the carriers were not available, these were kept segregated during school hours in a single classroom and forbidden to play with the other children. Two weeks after the second immunizing dose of 0.3 c.cm. of A.P.T., which was given on December 18, they were allowed to return to their normal school routine. No further cases of diphtheria occurred. The failure of this outbreak to assume epidemic proportions in spite of the high carrier rate is of some interest.

West Wycombe.—In August, 1940, 4 cases of diphtheria occurred within a week in the local school. On Monday of the following week the school was visited. Nose and throat swabs were taken from 120 of the children and staff, and the children were given 0.1 c.cm. of A.P.T. and 500 units of antitoxin. Nine carriers of the gravis type of diphtheria bacillus were detected—1 nose, 6 throat, and 2 nose and throat. The carriers were isolated. A second dose of 0.3 c.cm. of A.P.T. was given a month later. No further cases of diphtheria occurred.

Discussion

The results described in these seven outbreaks of diphtheria are very promising. With one possible exception, a boy whose immunization record was incomplete, there was not a single case of diphtheria after the first dose of A.P.T. and serum; whereas at least four cases occurred in children who for one reason or another had not been immunized. It is of course impossible to say what would have happened in the absence of our intervention, but the fact that in two outbreaks several cases had occurred in the previous week, and that in five of the outbreaks a large number of carriers were detected, renders it probable that in some at least of the schools cases would have continued to develop.

The problem created by the intermediate period of relative susceptibility, discussed briefly in the introduction to this paper, appears to have been satisfactorily solved by the detection and segregation of the carriers in the community. Permitting them to return to school a fortnight after the other children had received their second dose of A.P.T., even though they were still carrying the diphtheria bacillus, was admittedly hazardous, but in practice it did not lead to the development of any fresh cases in immu-

nized children. Two cases did occur, however, in children who either had not been immunized at all or had been imperfectly immunized.

It seems clear that if carriers are to be allowed to return to school in six weeks the remainder of the school children should in the meantime have been adequately treated. With the active co-operation of medical officers of health, such as we have been privileged to enjoy, there should be little difficulty in ensuring that all, or practically all, the children are immunized. If for any reason this proved impossible, either the carriers or the non-immunized children would have to be kept out of school, depending on which was the smaller group.

Judging from Fjord-Nielsen's (1940) observations on guinea-pigs, it is possible that a greater and more rapid degree of immunity might be obtained if a second dose of A.P.T. was given two weeks after the first combined injection, and a third dose a fortnight later. This would necessitate an extra visit for the immunizing staff, but it might render safe the liberation of the carriers within four instead of six weeks. No data, however, are available on this point, and it would be wise to make careful observations on the antitoxin production of non-contacts treated by this method before applying it to the control of epidemics in the field. Meanwhile, in view of Glenny, Buttle, and Stevens's (1931) observations, it would probably be sound practice, in order to ensure a greater amount of unneutralized toxoid remaining after the first injection, to increase the first dose of A.P.T. from 0.1 c.cm. to 0.3 c.cm.

It is curious that the method we advocate in this paper—namely, the use of active and passive immunization, and the detection of carriers and their isolation for six weeks—does not seem to have been employed previously, though each has been tried by itself. Ramon (1940), for example, states that the treatment of diphtheria contacts by combined active and passive immunization has been used extensively in France, but he mentions nothing about the detection and isolation of carriers, nor does he give any record of the results obtained. Gierthmühlen and Voges (1939) used the method of combined active and passive immunization in a school epidemic near Hamburg, but as they likewise paid no attention to possible carriers it is not surprising that a number of cases developed after passive immunity had worn off and before active immunity had become sufficiently established. Martin, Loiseau, and Laffaille (1928) used combined active and passive immunization for 14 school contacts, but again they did not attempt to remove the carriers. Okell, Eagleton, and O'Brien (1924), on the other hand, recommend the isolation of carriers but rely exclusively on active immunization of the Schick-positive contacts. The weakness of this method consists in wasting time over the Schick test and in affording no protection to susceptible children who are already infected or who contract infection before the carriers are removed. It would seem that if an outbreak of diphtheria is to be stopped at once, and that if further cases developing from exposure to infection after passive immunity has worn off are to be prevented, both combined active and passive immunization and the detection and isolation of carriers are necessary.

Summary and Conclusions

A method is described for bringing outbreaks of diphtheria in closed or semi-closed communities to an abrupt end.

The method consists essentially in (a) giving combined active and passive immunization to all those exposed to risk, and (b) detecting and segregating carriers of the diph-

theria bacillus. Preliminary Schick-testing is neither necessary nor desirable.

The doses used in our work were 0.1 c.cm. of Burroughs Wellcome's A.P.T. and 350 to 500 units of refined diphtheria antitoxin for the first injection, and 0.3 c.cm. of A.P.T. for the second injection, four weeks later. It might be advisable, however, in future to increase the first dose of A.P.T. to 0.3 c.cm. and to give 500 units of antitoxin as a routine. Refined serum is advisable, because of the low proportion of serum reactions that follow its use. Carriers are immunized in the same way as the other children.

Six weeks after isolation—that is, two weeks after the rest of the school has received its second immunizing dose—the carriers can be liberated and allowed to mix freely with the other children, even though they are still infective. All new-comers must be immunized before entering the school or be kept segregated till they have been immunized.

This method was used in seven residential and non-residential schools in which diphtheria had broken out. The population at risk was about 1,500. In every instance the outbreak ceased immediately. Only five fresh cases are known to have occurred subsequent to the first combined injection: three of these were in children who were not immunized, one was in a child that did not receive its second dose of A.P.T. after four weeks, and one was in a child whose immunization record was defective.

These results are very promising, and it is hoped that other workers will give the method a trial. The fact that the children are protected at once by virtue of the serum injected renders closure of the school quite unnecessary. The saving of time, money, and inconvenience thus effected is too obvious to need stressing.

In outbreaks involving so many different administrative authorities it is impossible to accord due recognition to all the medical officers, head masters, health visitors, and school teachers who helped us. We should, however, like to mention particularly Dr. Campbell, M.O.H., West Oxfordshire Combined Districts; Dr. Rose of Wokingham; Dr. Warburton of Wallingford; Dr. Tangey, County M.O.H., and Dr. Blackley, Assistant County M.O.H., Wiltshire; Colonel Powell, M.O.H., borough of Chippenham; and Dr. Moore, M.O.H., borough of Chepping Wycombe. We are also greatly indebted to Miss D. M. Elliott for her care and help in keeping the records, and to our chief technician, Mr. J. D. Atkinson, whose forethought and continual watchfulness in arranging for the necessary provision of equipment cannot be praised too highly.

According to the *Klinische Wochenschrift* (May 5, 1941), large quantities of rose-hips, the vitamin C content of which is ten times that of lemons, have been collected in Bulgaria. Roughly seven times the quantity gathered in the same period in Germany was obtained for Germany by a common organization in the two countries. The hips were dried, ground, and packed in Bulgaria, and were sent to Germany to be prepared for consumption. During the months of April and May the hips are to be distributed for sale among selected towns in accordance with instructions issued by the Reich Ministry of Health and the Reich Ministry of Food. Half of them will be given to the troops in Norway and sailors of the fleet, who are in special need of vitamin C, and the hospitals will also receive some!

INDUSTRIAL MEDICAL SERVICES IN GREAT BRITAIN A CRITICAL SURVEY

BY
DONALD STEWART, M.D., F.R.C.P.Ed.
*Consulting Medical Officer, the Austin Motor Company, the
General Electric Company, and Guest, Keen, and
Nettlefolds Limited*

Problems of 1914-18

It is an interesting fact and a sidelight on British mentality that the significance of industrial health and its relative importance in the scheme of things has been generally appreciated only when the country has been in a state of extreme emergency—namely, in the great war of 1914-18, and again in the present war. At the end of 1915 an unparallelled health problem was created because of the massing together of large numbers of munition workers—very many of them women—their abnormal hours of work, the intensive speeding up of production, and labour unrest generally. Fatigue became a primary cause of absenteeism and definitely interfered with the war effort, and the Government was therefore forced to take action. Lloyd George set up what he termed the Health of Munition Workers Committee "to consider and advise on questions of industrial fatigue, hours of labour, and other matters affecting the health and physical efficiency of workers in munition factories and workshops," and the results of its investigations are reported to have done much to improve conditions. This committee was replaced at the end of 1918 by the Industrial Fatigue Research Board. The Board is responsible to the Medical Research Council, which in turn is under the control of the King's Privy Council. An account of the work of the committee and the Board, known from 1928 onwards as the Industrial Health Research Board, has recently been published (Vernon, 1940) with particular reference to present-day health problems in factories.

Developments after 1918

Much of the pioneer work of the Health of Munition Workers Committee was either forgotten or disregarded after the war, and a general apathy developed on the part of both employers and organized labour regarding health matters. Academic research was continued by the Industrial Fatigue Research Board, but these efforts were rarely translated into practice. With trade revival in 1923 and during the next three or four years a number of the larger firms in England developed their own medical services—for example, Boots Pure Drug Company, the Chloride Electrical Storage Company, the Mond Nickel Company, J. Lyons and Co., and Imperial Chemical Industries Limited. By 1927 the number of whole-time industrial doctors was probably about 20 in all, including those employed by the General Post Office (Bashford, 1938), and Woolwich Arsenal, two large Government-owned industrial concerns which for many years before 1914 had whole-time medical officers. There was a gradual increase up to 1935, when the demand for contact and mutual help between doctors doing this type of work resulted in the formation of the first British scientific society in connexion with industrial medicine—the Association of Industrial Medical Officers. This association soon increased its membership, and the subject of health in industry began to take its place as a specialized branch of medicine, due largely to the pioneer work of Howard Mummary, Lane, and Lockhart; a branch which soon proved to link up closely with the work of the general practitioner and hospital specialists, and to be in its turn but a part of social medicine and the

practice of public health. Regard must also be given to the work of Hyde and the Industrial Welfare Society in connexion. His efforts from the earliest days to forward the case for industrial medical service in the country.

Developments in this War

In September, 1939, there were some 60 whole-time industrial medical officers in England and, so far as is known, only one in Scotland, but it was not until the introduction of the Factory (Welfare and Medical Services) Order, 1940—a direct result of the appointment of Ernest Brown as Minister of Labour—that industry and the medical profession both realized that the Cinderella of our services had been given a place in the front rank. Then there has been a rapid development, and it is estimated that to-day there are over 150 whole-time and over 500 part-time medical officers employed by factories in Great Britain, practically all of them in factories. Of the part-time doctors are also factory examiners, appointed by central Government under the Factory Act, mainly to examine all juveniles under 16 years of age, in industrial factories and to give certificates in connexion with industrial diseases.

A similar impetus to industrial nursing was given by this Order. Not only have employers had to appoint industrial nurses but even more frequently they have been asked to appoint nurses. The Ministry of Labour, acting in collaboration with the Royal College of Nursing, has taken the training of nurses wishing to enter industry, has advised that factories making new appointments should, wherever possible, employ fully trained registered nurses. This is an advance of some significance, replacing as it does the old conception that a woman could become a capable factory nurse simply by gradually widening, and in the smaller units in particular, those employing fewer than 1,000 persons—her scope is becoming more closely associated with preventive medicine and public health.

Why is there a Need for Industrial Health Services?

The term "industrial health" is not confined solely to a state of bodily and mental fitness in the individual, but includes what is really the state of the public health as regards groups of employees, both small and large. Productive capacity and output are dependent on health, and the economic status of any country is therefore closely related to the physical and mental well-being of its workers. The present health and mental well-being of its workers. The National Health Insurance Scheme, the fields of general and consultant practice, hospital services, and municipal and Government health services—do not cater fully for the varying physical and psychological factors within factories and business organizations which can so profoundly affect health. There are therefore in the nation's health service certain gaps which can be bridged only by the appointment of industrial medical officers and by the formulation of a comprehensive industrial medical policy as part of the general health services of the country. The more important of these gaps are as follows:

1. The First Treatment of Men and Women Injured or becoming Sick while Actually at Work

Hitherto this part of treatment has been mainly in the hands of persons with doubtful qualifications, first-aid workers of all types, and untrained nurses. Even where fully trained nurses are employed there is often no medical supervision of their work, and incidentally this is probably the only branch of nursing in which there can be a complete absence of medical

control. Because of this, casualty and first-aid services in industry have developed slowly and unsatisfactorily. For example, over 11% of all injuries reported* to the Factory Department in 1939 were septic. This is due not only to a lowering of individual resistance to infection and to carelessness in reporting so-called trivial injuries but also to the comparatively low standard of equipment required by the Factories Act, and the absence of any standard of treatment except a statement (Section 45) that the person carrying out this work in factories employing more than 50 persons shall be "a responsible person trained in first aid." The present first-aid organizations in Great Britain do not cater specially for this type of training, but the British Medical Association has considered the matter constructively and in some detail in a special report (1939).

Where a medical officer and trained nurses are appointed to a firm it has been proved that there is an immediate return to both the employer and the employee through the marked increase in the efficiency of the first treatment services. One proof of this is the reduction of sepsis that can rapidly be brought about (Stewart, 1939).

2. Medical Supervision of the Return to Work of Sick and Injured Employees

Sick and injured workers are often sent back to their jobs too soon and in a state of sub-fitness which for some considerable time makes it difficult for them to be really efficient; and, again, it may be that the doctor keeps a man or woman off work too long, and for that reason earning capacity is interfered with and production unconsciously retarded. The fact is that the majority of medical men and women have a scanty knowledge of the physical and mental requirements of the occupations of their patients: the return to work is determined by rough-and-ready hit-or-miss methods, and rehabilitation in the fullest sense of the term is a closed book to a great many of them.

The industrial medical officer who acquires an extensive and accurate knowledge of the different occupations in his industry can be of great help to medical practitioners and hospital authorities in assessing capacity for work. His part in rehabilitation is as essential as that of any occupational therapy clinic, and proof of this lies in the fact that where an industrial medical officer is employed the process of return to work is facilitated, to the greater satisfaction of both the worker himself and his employer. There is an opportunity for continued supervision under working conditions, of obtaining true alternative or "light" occupation during the tuning-up process, of giving supplementary treatment in the factory clinic while the man is at work, and of obtaining for the workman a degree of indulgence from his supervisor for a short period which is so essential in completing rehabilitation. In any scheme for the setting up of accident hospitals, such as that already started at Birmingham, the position of the industrial medical officer as an essential part of the service must not be overlooked.

The implications of this side of his work are wider than is perhaps realized at first. During illness the patient consciously or subconsciously wishes to maintain some contact with his employer because of an inherent sense of insecurity, and particularly so if illness is prolonged, because there are limits to which financial assistance can be given, even if based on insurance methods; and so the industrial medical officer can be of assistance not only to sick and injured workers but to general practitioners, specialists, and hospital officers as their medium of contact with the employer on behalf of their patients. Because of his neutral position he can conserve a certain balance between employers and labour, and by so doing can build up good will and make a contribution of importance to industrial relationships.

3. The Effect of Working Environment on Health in Relation to Preventive Medicine

Because the medical profession knows so little of what goes on inside industry it becomes imperative that knowledge gained in the field of industrial medicine should be widely disseminated and the fullest facilities for education and research made avail-

* A "reportable" accident is one which has caused an absence from work of three days or more. (See Annual Reports of the Chief Inspector of Factories.)

able to the medical profession. The unique opportunities now afforded to many hundreds of doctors for preventive work within the factory walls will be wasted for future generations if some scheme of co-ordination is not evolved. Practical research into the prevention of accidents, industrial diseases, and sick-absenteeism generally, all offer scope for the best brains of the profession on economic grounds alone, apart from the value to the individual worker and the health of the nation.

Much research work, which before this war was of its kind outstanding in the world of scientific medicine, has been carried out by the Industrial Health Research Board. This work has included studies on hours of labour; environmental conditions in the factory, such as lighting, heating, and ventilation; dusts and toxic vapours; and the physiology and psychology of work. Each annual report in itself is a comprehensive document, and the individual reports on these various subjects are unique in their respective fields. Nevertheless there has been the greatest difficulty in having the results of the Board's investigations put into actual practice in British industry—a difficulty which the Board itself has recognized. It may be that terms of reference preclude it from propaganda and advertisement, but it is more urgent now than ever before to form some policy which will enable the results of health research work from all sources to become embodied as an essential part of industrial management. For example, industry should have some authoritative statement at an early date regarding the vexed questions of the use in industry of vitamins, physiotherapy, and inoculation in the prevention of the common cold and its derivatives, generally accepted to be the most frequent cause of sick absence in factories.

The Factories Act (1937) is a document of great significance. Its trend and appeal are towards an improvement of health; and as a contribution to preventive medicine its potential importance has perhaps as yet not been fully realized. Suggestions regarding medical supervision of factories are laid down in a pamphlet recently published by the Ministry of Labour (1940), which also will repay close consideration. And how industrial health is influenced by war conditions is described in an emergency report of the Industrial Health Research Board (1939). But perhaps the fullest account of the position in the country before September, 1939—an account not only of industrial health but of the British health services as a whole—is contained in a comprehensive report published by Political and Economic Planning in 1937.

The B.M.A. Medical Planning Commission, set up recently to consider the present and future development of Britain's health services, will undoubtedly have much to do with industrial health, especially with its relation to other branches of medicine. The suggestions of the Commission are to be fully considered at every stage by the profession as a whole, for it is only by the help of open and frank constructive criticism from all parties that any comprehensive scheme to meet the needs of the community can be evolved satisfactorily and put into practice.

What is the Nature of the Present Service?

Our present industrial medical services are mainly in factories and are for the most part voluntary in nature, medical officers being appointed and paid by the employer. There is no control, therefore, either by the medical profession itself or by the State, over the development of this type of service. The efforts of individual factory doctors have done much to improve health in industry, but mainly in the larger firms which could afford the service; and because of the lack of a suitable propaganda medium these benefits have often not been fully available for the great mass of workers.

There has been only a sporadic attempt to arrange for any training of the many new medical officers appointed to factories, nor is there any provision for education in the health problems of mines, the transport industry, or shipping. With the exception of London and Manchester the universities have done little to help. Birmingham University in 1935 set up a Department of Industrial Medicine, which for a number of reasons was closed in 1938; and because of the demand from individual doctors Manchester, Birmingham, and Sheffield Universities have within recent months organized successful week-end courses of training. The methods of selection and appointment of new industrial medical officers under the present system are open to criticism. Salaries and conditions of appointment vary greatly, and some general practitioners obtaining part-time appointments do so without much interest in industry; nor, with the responsibilities of a large general practice as their major problem, have they the time to develop this work.

The main way in which the State has come into the picture is because firms have been recommended and in some cases forced to appoint whole-time and part-time industrial medical officers by the Factory Department of the Ministry of Labour under the Factory (Medical and Welfare Services) Order, acting on behalf of the Minister of Labour. The Department has no say in how these services should be developed, but has given suggestions in the Memorandum on Medical Supervision in Factories already referred to.

The Factory Department itself has on its staff thirteen medical inspectors under the supervision of a senior medical inspector. These doctors are grouped regionally and supervise the statutory aspects of health in the 250,000-odd factories throughout the country. They work in close liaison with the lay inspectors, and have been helpful both to medical officers entering industry and to employers who have had to introduce medical and nursing services into their factories. Because of their extensive knowledge and experience of factory conditions they play an important part in the prevention of occupational diseases, and much of the success in eliminating these diseases from British industry in the past fifteen years has been due to their efforts.

The Ministry of Supply has since the start of the war set up its own medical service under a Chief Medical Officer, who is responsible for the administration and policy of the health services for all Government-owned factories in the control of the Ministry. Already he has under him 50 whole-time and a large number of part-time medical officers situated in various parts of the country, so what is really the first State-controlled medical service in the history of British medicine has now been set up, and its development will be watched with considerable interest.

The Mines Department has only one medical inspector, but a number of colliery owners and insurance companies interested in compensation problems among miners—for example, accident treatment and silicosis—have appointed their own doctors to supervise health conditions in mines. The Silicosis and Asbestosis Board is a body of doctors grouped regionally and appointed primarily to examine suspected cases from the point of view of capacity for work and compensation claims, but its individual members have been of considerable help to employers in the prevention of these diseases in industry.

Medical officers of health have little to do with health in factories, although it is a significant fact that local authorities are themselves often large employers of labour. The Ministry of Health has so far taken little part in industrial problems, being forced by circumstances to leave

the matter largely in the hands of the Factory Department of the Ministry of Labour.

Relation of Industrial Medical Service to General Practitioners and Hospital Services

This relation was the subject of considerable controversy during 1935 and 1936, and a special committee of the British Medical Association was appointed to discuss the matter. As a result a set of ethical rules was drawn up by both sides, and these on the whole have operated satisfactorily from that time. In 1940 the Association appointed an Industrial Health Committee "to further the co-ordination of industrial medical practice with other forms of medical practice, in particular with general practice and the public health and hospital services," and its first report will be issued shortly.

Relations between general practitioners and industrial medical officers throughout the country are good, particularly in the case of whole-time medical officers. Where part-time medical officers who themselves are also general practitioners are employed there is evidence that relations are not always fully satisfactory or of the happiest. This is particularly noticeable where the part-time works doctor has an appointment in his own area and where he may unconsciously attract members of the works and staff of his factory to his private practice. The question of part-time medical service in industry is one of importance and must be closely considered in planning for the future, because a large proportion of the working population is employed in units of 250 or less. There is one view which suggests that industrial medical service after the war should be linked up with general practice, and another which maintains that an industrial medical service should be set up consisting of specially trained personnel who would devote the whole of their time to this type of work.

Hospital authorities have so far given little consideration to the effect of work and working environment on their patients' lives, especially in relation to the rehabilitation of the sick and injured. Schemes are on foot for improving conditions in hospitals with particular regard to the treatment of accidents, and a memorandum drawn up by the Birmingham Accident Hospital (1941) for industrial concerns in the Midlands brings out some of these points very clearly.

The Worker's Point of View

During the past ten years there have been complaints from individual workers and from organized labour about the employers' methods in connexion with the medical examination of workers. It was strongly felt that factory medical officers were essentially on the employer's side because they were appointed and paid by him; that they therefore had a biased outlook; and that if a man was found by medical examination to be unfit for certain work and this was disclosed to the employer, it would lead in many cases to injustice being done and in the end outweigh all the potential value of industrial medical services. But when the doctor understands the problem of relationships and has a reasonable outlook, and when he is fearless in his statements and gives opinions founded on accurate facts and observations, his position is soon recognized by employer and employees alike to be that of one entirely uninfluenced by the vested interests of either party, and his opinion is fully accepted by both sides in any matter to do with health. It is only by obtaining this bilateral confidence that the industrial medical officer can be successful in his work.

The Employer's Point of View

There are many employers in the country to-day who fully agree with the introduction of industrial medical ser-

vice and have welcomed its increase. They realize the economic value of such service and acknowledge that they have a responsibility in management beyond that of being merely custodians of the shareholders' money. This outlook is encouraging and provides greater reason for confidence that the service must have a place of no little importance in any future health planning for the nation. On the other hand there are still employers of labour who consider that the health of their employees is little or none of their business; they are prepared to fulfil the letter of the law and keep their statutory obligations, but are unwilling to go further. Where doctors are appointed under the new Order to such firms they have a great responsibility. They have to prove to the employer that the service they are giving is helpful not only to the workers but to industry as a whole, and one not lightly to be discarded after the war.

"ETHER CONVULSIONS"

BY

H. J. BRENNAN, M.D., D.A.

Anaesthetist, Manchester Royal Infirmary; Temporary Major, R.A.M.C.

"Ether convulsions" were described simultaneously in May, 1927, by two Manchester anaesthetists—K. B. Pinson (1927) and the late S. R. Wilson (1927). Pinson thought them to be due to an over-accumulation of CO₂. This explanation has never been generally accepted, for not only have convulsions occurred during endotracheal administrations, when the alveolar CO₂ content is at its lowest, but the administration of CO₂ has been found an effective method of treatment. Wilson, on the other hand, attributed the convulsions to impurities in the ether, aldehydes and peroxides having been detected in the samples used. Walton (1928) found impurities which supported Wilson's theory, but Sykes (1930) and Ross Mackenzie (1931) did not find them, or only in such minute quantities as to be negligible. This theory, however, received much attention both from the chemical houses producing ether and from the makers of anaesthetic apparatus. It became customary to sell ether in dark-coloured bottles wrapped in black paper, and the ether bottles of some anaesthetic apparatus were made of heavily tinted glass. Later, copper was found to be a powerful anticatalytic agent, and the tubes which dip into the ether in Boyle's and similar machines were subsequently made of this metal. In spite of these precautions convulsions still occurred, and it has long been generally accepted that impure ether could not be regarded as their cause. Conclusive evidence of the correctness of this view is the fact that typical "ether convulsions" have

occurred when no ether has been used—for example, during operations under local (Hudson, 1936), chloroform (Bull, 1927), and nitrous-oxide-oxygen anaesthesia (Sington, 1927).

When the convulsions were first described it was uncharitably suggested that these new and extraordinary phenomena might be due to faulty provincial technique. As reports were published of similar convulsions having been seen in all parts of the country this explanation had quickly to be abandoned, but, as will appear later in this paper, I consider the frequency with which they have occurred in Manchester to have a definite aetiological significance.

Since Pinson and Wilson first described this condition much has been written on the subject. Many case reports have appeared and numerous theories have been advanced, though none of them has been universally accepted. This is possibly because no one theory has explained and fitted in with all the known facts and the many observations that have been made. It is common knowledge, however, that the combination of youth, heat, and a septic condition with pyrexia occurs in some 85% of cases, and on this account the heat-stroke theory, first put forward by Dickson Wright (1935) and upheld by Woolmer and Taylor (1936), has received more support than any other. It is proposed in the present paper to support and elaborate both this theory and that of neurogenic shock advanced by Hudson (1936) and to explain the occurrence of the hyperpyrexia.

I suggest that ether convulsions are caused by a strong neurogenic stimulus in a hyperpyrexial patient. I consider that the hyperpyrexia is due to the administration of a general anaesthetic to a dehydrated pyrexial subject in a hot humid atmosphere, the subsequent rise in temperature possibly being increased by the previous administration of atropine.

Neurogenic Stimuli

In the cases recorded in Hudson's valuable paper the convulsions were undoubtedly initiated by neurogenic stimuli. This is equally true of a case reported verbally to the Anaesthetic Section of the Royal Society of Medicine. The last-mentioned patient was being given nitrous-oxide-oxygen for a thyroidectomy and had been premedicated with omnopon-scopolamine. The surgeon pulled rather hard to expose the upper pole, and convulsions started immediately. These settled in a minute or two, the operation was continued, and the surgeon repeated his over-forceful manoeuvre, whereupon the convulsions immediately restarted.

The exact stage of the operation at which convulsions began has unfortunately not been mentioned in all the published case reports. In the majority of those in which it has been recorded one cannot but be struck by such oft-recurring phrases as "just as the peritoneum was being opened" or "while the peritoneum was being shut"—i.e., while the peritoneum was being lifted upwards, possibly rather forcibly. Again, in two or three cases bone chiselling was taking place at the moment of onset. I have seen one case in which convulsions started the moment the peritoneum was picked up by forceps previous to incision. The convulsions were controlled and the operation continued. The convulsions restarted when the peritoneum was picked up again as a preliminary to closure. I have seen another case in which the convulsions definitely started just as cross-action peritoneal forceps were applied. Yet another case of mine showed this initiating nociceptor factor even more dramatically.

The patient, a boy aged 8, was suffering from an acute mediastinitis due to a swallowed pin, which had passed through the oesophagus. He was extremely ill, was badly dehydrated,

and had a temperature of 103.8° F. I gave him nitrous oxide, oxygen, and ether from a Boyle machine via a Magill tube. The posterior mediastinum was opened under very light anaesthesia. The surgeon saw the pin at the bottom of the wound and turned round to choose a suitable instrument with which to extract it. Meanwhile his assistant unfortunately inserted and pulled on a deep retractor. The boy's pulse immediately halved its rate, and within a few seconds he experienced typical violent generalized convulsions.

It must be emphasized that it is not considered that neurogenic stimuli alone will cause convulsions. Every year thousands of patients receive gross peritoneal and other nervous insults without showing any alarming symptoms. But in the presence of hyperpyrexia, whether or not a general anaesthetic has been given, severe neurogenic stimuli are apt to initiate convulsive symptoms, though admittedly the latter very occasionally may occur without the patient having received any sensory stimuli—e.g., before the start of the operation.

The nature of the underlying biochemical change associated with the hyperpyrexia and predisposing to convulsions is not at present understood, though in this connexion the alteration of the wave-and-spike electrical activity of petit mal resulting from changes in blood-sugar concentrations (Gibbs, Gibbs, and Lennox, 1939) is of interest and worthy of further study.

Hyperpyrexia

There is a considerable volume of evidence in the literature that hyperpyrexia is present in patients who have had ether convulsions. I can add to this record two cases in which I found rectal temperatures of 108° and 108.5° F. immediately after short convulsions.

The possible factors leading to this hyperpyrexia must be carefully considered. In a typical case of ether convulsions the patient is 5 to 15 years of age and is suffering from an acute septic condition—often an acute appendicitis of forty-eight hours' standing. He has a raised body temperature and the weather is hot. All these factors, with the common addition of vomiting and reduction in fluid intake, combine to cause a severe degree of dehydration.

It was considered in the past that simultaneously with a rise in the skin temperature of the extremities (Scott and Morton, 1931) a fall in body temperature occurred under ether anaesthesia. Watkins and Wilson (1927) showed, however, that this was true only of quiescent-interval cases, and that in acute cases in dehydrated subjects body temperature rose during ether anaesthesia. I have repeated, and confirmed, the latter observation on a series of patients.

I have found that a dehydrated subject with a temperature of, say, 101° F. who is given a general anaesthetic is, particularly if young, likely, under the best conditions as regards theatre ventilation, to return to the ward with a temperature about 2° higher. If theatre conditions are not optimal his temperature may rise considerably more. The association between hot weather and ether convulsions has often been noted. As has been mentioned, hot weather can exert an influence by increasing the patient's pre-operative dehydration. It can also raise the temperature of old-fashioned theatres. The temperature of the theatre is not, however, of very great importance *per se*. It is the wet-bulb temperature and the relative humidity which matter. Hamilton Bailey (1940) recently cast doubt upon the heat-stroke theory when reporting two cases which occurred in extremely cold weather. Without a record of the wet-bulb temperatures of the theatres this observation does not carry much weight.

On two occasions I have been able to measure the wet-bulb temperatures of theatres immediately after ether con-

vulsions had occurred, and found readings of 78° and 79° F., the latter being only 1° F. less than the temperature at which, under Board of Trade regulations, cotton factories must be evacuated. Every degree rise in wet-bulb temperature reduces the amount of heat which the body can lose. It follows that if a dehydrated pyrexial young subject is anaesthetized in a hot humid theatre the expected rise in temperature of 2° to 3° F. may be greatly exceeded. I would suggest that this is the reason why Manchester has seen such a regrettable number of ether convulsions, the prevailing humidity being notorious.

In this connexion it is interesting to note that no case of ether convulsions has occurred in any of five busy air-conditioned theatres in that city since they were built six years ago.

Atropine

Hornabrook (1927) first suggested that large doses of atropine were the chief cause of ether convulsions. Singleton (1927) rather refuted this idea on the evidence of the Hospital for Sick Children, Great Ormond Street, where 7,000 children are operated on each year and where all receive large doses of atropine. While there is no evidence that atropine ever acts directly as a convulsive agent in these cases, as Hornabrook suggested, but rather the reverse, it is possible that it does contribute to the hyperpyrexia.

Observations were made on the effect of atropine on the rise of body temperature which occurs in a hot atmosphere with a high-percentage saturation of moisture. Three subjects sat for twenty minutes in a room of a Russian bath. When they had cooled down again each was given 1.60 grain of atropine subcutaneously. Half an hour later they sat for another twenty minutes in the Russian bath. Their temperatures on the different occasions are given below:

	I	II	III
Before experiment	97°	97.4°	97°
After 20 minutes in Russian bath	100°	100.4°	100.2°
Return to normal	97°	97.6°	95°
After 20 minutes in Russian bath 1/2 hour after injection of atropine	100.6°	101.3°	101.3°

These results showed that the very hot humid atmosphere caused a slightly greater rise in body temperature after the administration of atropine. Incidentally the atropine also caused a very marked and unpleasant exaggeration of the subjective symptoms.

Treatment

Acceptance of these theories opens up a definite line of treatment which must primarily be preventive. This dangerous complication can be very largely averted, and particular care should be taken to remove the exciting factors in those subjects in whom the onset of the condition might be feared.

1. The dehydrated pyrexial young patient should be put on a glucose-saline drip before operation, and anaesthesia should not be induced until at least 1 to 2 pints have been given.

2. All new theatres should, of course, be air-conditioned. Apart from this, much may be done to improve existing theatres by the use of extractor fans, air vents, steam condensers, removal of sterilizers outside theatres, and similar steps. A wet-and-dry-bulb thermometer should be found in every general theatre, and an anaesthetist should normally refuse to induce a dehydrated young patient if the wet-bulb temperature is over 70° F.

3. It is unnecessary to emphasize here the importance of gentle surgery and of avoiding neurogenic trauma. So far as the anaesthetist is concerned, he should see that the depth of anaesthesia is always adequate for the stage of the operation in progress.

4. Heavy mackintosh coverings should not be used.

twice in hospital for "chorea" (the diagnosis is doubtful). Her intelligence is slightly below the average. She is pleasant, friendly, inclined to moodiness and temper, and normally sociable, but looks pale and tired. She made twenty-two attendances at the clinic during February to May, 1938. The incontinence stopped a few weeks after she started treatment, and she began to look cleaner and brighter. Her play showed a conflict of feelings of various kinds, such as inferiority and self-assertiveness; jealousy, together with the inhibition of natural aggression; and sex curiosity. She was able to understand through her play how the opposing sides of her personality were causing profound maladjustments towards both her family and herself.

As the home situation could not be altered and she was "out-growing her strength," it was decided to give her a year or so at a residential open-air school. Later on, after leaving school, she had a difficult period owing to conditions at home, but managed to survive it.

In this case incontinence was evidently a form of aggression against an intolerable home situation.

When prolonged into adolescence the condition is especially distressing to the patient, particularly in girls. The following case illustrates a probable association with suppressed sex curiosity and desire:

A girl aged 15 was referred for wandering and staying out at night; she was said to go out with soldiers and to spend nights in air-raid shelters. She suffered from faecal incontinence, which occurred only when she stayed out late in the evenings. She was the younger of two daughters, the elder one being the model girl. The parents were a mixture of hardness and sentimentality. With friendly interest at the clinic the incontinence stopped, and an attempt was made to get her away to suitable training.

The association of this symptom with sexual maladjustment or sexual "habits" is understandable as a regression to early sex development, and particularly the fantasy association between the process of birth and defaecation. This appeared to be vividly illustrated in the following case:

A girl aged 8 was referred to the child guidance clinic by the head teacher with the story that the child deposited her faeces in odd places, such as a corner of the school cloakroom, and, moreover, arranged scarves, bits of wool, etc., like a nest around them. The child, who lived alone with her mother, had recently discovered that a new baby was expected. The mother was in bed, and the girl was naturally having a difficult life. As something had to be done urgently, arrangements were made to get her away for a time. It was subsequently found that she had been unwanted; the mother was a very unreliable person, and the father worse. The complaint stopped as soon as the child got away from home into happy friendly surroundings, but she was described as a bit "queer" and not making friends easily. Unfortunately, owing to frequent changes of address, the case could not be followed up.

The association between the feelings of this child, unwanted (as later events proved) and expecting the advent of a rival, and the attempt which she made symbolically (as well as very realistically!) to give birth herself to something, which she treated as though it were a baby, appears fairly obvious.

The next case is one in which the condition, also associated with depositing faeces in curious places, yielded surprisingly quickly to removal from home for a short time.

This case was that of a boy aged 10 in whom the trouble had arisen only eighteen months previously. His incontinence was accompanied by various methods of disposing of the faeces—by plastering the walls, putting them in his pocket, etc. The situation at home was that he had a second stepmother, who was well-meaning but neurotic and disagreed with the father over the boy. There was a younger stepbrother (the son of the first stepmother), of whom the boy was jealous. He was of

average intelligence and had a good school report. The complaint ceased when he was boarded out on a farm. A few weeks later the parents took him home on some trivial excuse, but the trouble did not recur, and he was well when seen a year later.

Finally, here is a case illustrating an association of faecal incontinence with attacks of what may probably be described as pyknolepsy.

A boy aged 11 was referred from hospital in April, 1938, for enuresis and faecal incontinence. He was free from both while in hospital for two weeks. His father is normal; the mother has migraine. He was born after a gap of seven years, and has four older sisters and one younger brother. He had always had enuresis and was spoilt as a baby. He began soiling his trousers when he started school, and was smacked at first.

"Turns" which resembled petit mal began three years ago, and now occur frequently during the day. He is backward, and his intelligence is below the average. He is shunned or teased by other children. Soon after starting attendance at the clinic the enuresis stopped, and two months later the incontinence also stopped. His play showed much repressed aggression, and the world was to him a place full of danger. He remembered being tied down in his pram as a baby.

He relapsed, and spent some time at an open-air school, but did not sustain the previous improvement. No apparent reason was found for these relapses, and attempts to gain the further co-operation of the parents have failed.

Aetiology

Encopresis is primarily a psychogenic disorder. It is a physical symptom which appears, in response to certain psychological situations, in children who are in some way constitutionally predisposed to the particular response. Apart from the aetiological factors constantly found in the environment, proof of its psychogenic nature is furnished by the cessation of the complaint when psychological means such as reassurance, explanation, alteration of environment, etc., are applied. It is, generally speaking, a protest against an inimical and threatening environment: an unconscious reaction, both of aggression and of fear. The details of the mental mechanism and fantasies involved, though of great interest from the psycho-analytic point of view, are too complex for discussion here.

With regard to the physiology of the condition, it would seem as though the emotional tension operated by cutting out the voluntary control of the excretory mechanism and reducing it to a spinal reflex. It would be, in this sense, a hysteric mechanism of dissociation.

In all such psychosomatic symptoms it is obvious that, however predominant a part the psychological side may play, physical aspects and measures must not be neglected. Some cases of apparent incontinence, for example, are more in the nature of lenteric diarrhoea, while others may actually need treatment for constipation. It is a fact, however, that most cases are associated with normal evacuation.

Treatment

The treatment may be summarized as follows. Whereas full psychological treatment at a clinic may be desirable, it is often not obtainable; but all measures are in a sense psychological.

1. An inquiry by the doctor into the child's background, habits, etc., may reveal something which needs to be put right—e.g., the child may be worrying over school. The doctor who has an intimate knowledge of the family should score in this respect. Advice may be accompanied by medicine both for its actual effect (e.g., *pulv. cretae*) and as a vehicle for suggestion, if its properties are emphasized to the child and parent. Some of the cases, however, are actually constipated, and this must be carefully inquired into.

2. As regards psychological treatment, this will follow the usual lines of child guidance. Direct treatment aimed at removal of the symptom, by suggestion or other means, is, in my opinion, desirable in many cases, as it eases the situation considerably for both parent and child, and further treatment can be carried on for the neurosis as a whole. This will generally be in the nature of play therapy, depending on the technique employed. In adolescents, vocational guidance is usually necessary, as well as readjustment of their attitude to their problems. It must be pointed out, however, that prolonged treatment is not required in all cases. For many of them the symptom can be cured in two or three interviews or by simple environmental readjustment.

3. Very good results can be obtained in an institution provided it is of the right type. A residential open-air school has cured some of the cases first seen at the child guidance clinic. Others are cured at hostels for evacuated children. Everything, however, depends on the good relation between staff and children. At the school mentioned above remedial exercises to strengthen the abdominal and pelvic muscles were considered useful.

4. If simple measures fail a period of observation in hospital may be advisable, both to eliminate organic disorder and because it may effect a salutary break, and show the child and the parent that the habit can stop (just as asthmatic, epileptic, and other attacks often disappear while the child is in hospital).

Summary

An inquiry is made into the investigation and treatment of encopresis in children based on cases treated at the Birmingham Child Guidance Clinic over the past seven years.

No definite organic condition is found, and the cause is held to be psychogenic, the symptom being a regressive one.

Examples of cases and a summary of various lines of treatment are given.

My thanks are due to Miss A. McClure, Miss T. Alcock, and Dr. S. Isaacs for their observations and suggestions.

MACROCYTIC ANAEMIA FOLLOWING GASTRO-ENTEROSTOMY

BY

NEIL S. GORDON, M.B., Ch.B.

House-physician, Royal Infirmary, Edinburgh

AND

JÓZEF JAPA, Dr. Med.

Late Clinical Assistant at the University in Lwów

The following two cases seem to be of some clinical interest. Both men developed a macrocytic anaemia after gastro-enterostomy. The first had had an operation for duodenal ulcer eleven years ago, and now shows a hyperchromic macrocytic anaemia which coexists with the hyperacidity of the gastric juice. The second patient developed a severe hyperchromic anaemia with some features of pernicious anaemia after a gastro-enterostomy performed twenty-eight years ago. He recovered without incident after liver therapy. Owing to the long time since the operation it is impossible to state definitely in this latter case if the present anaemia arose in connexion with the previous operation or if it is a separate entity.

Case Reports

Case 1.—A miner aged 52. Eleven years ago he was operated on for duodenal ulcer, a posterior gastro-enterostomy being done. The fractional test meal before the operation showed hyperacidity. Since then he has had little trouble, only occasionally having slight attacks of pain; lately, however, the pain has been worse, and is accompanied by vomiting. On examination pallor of the skin, a slightly enlarged spleen, and tenderness in the epigastrium were found. A radiograph revealed a normally functioning gastro-enterostomy with some ulcer deformity in the duodenum; there was no ulcer crater. Fractional test meal: fasting juice volume 40 c.cm.

	Fasting	1	1½	2	2½	3 hrs.
Free HCl	35	10	40	45	35	25
Total acidity	45	25	55	55	45	35
						35 N/10 NaOH as % of HCl

Blood examination showed: red cells, 1,630,000 per c.mm.; haemoglobin, 40%; colour index, 1.25; macrocytosis; white cells, 10,000 per c.mm.—polymorphs 69%, eosinophils 4%, basophils 1%, lymphocytes 14%, monocytes 12%. Sternal puncture showed the bone marrow to be normal. Liver (permaemon) was given with good result.

Case 2.—A railway constable aged 62 complained of weakness and breathlessness on exertion. In 1912 a posterior gastro-enterostomy was performed for duodenal ulcer. Examination showed pallor of the skin, slight glossitis, sluggish knee- and ankle-jerks, but no enlargement of the spleen and liver. The fractional test meal showed no free HCl, the total acidity not exceeding 10; the fasting juice volume was 50 c.cm. Blood examination: red cells, 1,500,000 per c.mm.; haemoglobin, 55%; colour index, 1.8; macrocytosis; white cells, 3,000 per c.mm.—polymorphs 49%, eosinophils 6%, lymphocytes 42%, monocytes 3%. Normoblasts 7 per one hundred white cells; reticulocytes 2 per thousand. The fragility of the red corpuscles against hypotonic NaCl solution was normal—0.36 to 0.46%. Sternal puncture revealed an excessive number of large erythroblasts. Liver (permaemon) was given, and three weeks later examination of the blood showed a great improvement.

Commentary

The development of a hypochromic anaemia following simple gastro-enterostomy for gastric ulcer has been noted by many authors. This type of anaemia was reported by Witts (1930) in four cases, by Cosin and Hurst (1930) in one case, by Davies (1931) in five women and one man, by Lublin (1936) in 23 cases, by Meulengracht (1932) in one case, and by Hartfall (1934) in six women.

There are also much rarer reports of hyperchromic anaemia, sometimes called "megalocytic" anaemia, developing after gastro-enterostomy. Davidson (1928) described an Addisonian anaemia developing twenty months after gastro-enterostomy; Conybeare reported such a case in 1922; Hurst (1934) collected seven cases; Lublin mentioned this type of anaemia in one case two years after operation; and Fairley and Kilner (1931) reported one case of megalocytic anaemia following gastro-jejuno-stomy which eventually developed gastro-jejuno-colic fistula. Lastly, Salus (1932) reported two cases of subacute combined degeneration of the cord, without anaemia, fifteen years after gastro-jejuno-stomy.

The period in which the cases developed anaemia varies considerably—from twenty months to twenty-eight years after the operation. For the most part the anaemia occurred in women. Vaughan (1932) and others have stated that the anaemia may coexist with hyperacidity as in Case 1 above. They found normal acidity or hyperacidity in a certain proportion of cases after gastric operation even if severe anaemia was present.

The diagnosis of pernicious anaemia in the above cases is based on the blood picture (megalocytosis, colour index,

Notes on Books

Contraception: Its Theory, History, and Practice, as surveyed by MARIE STOPES, D.Sc., Ph.D., contains a great deal of information, not all of equal importance, upon the subject. In the preface to the fifth edition the pioneer's enthusiasm still shines. Peace is founded on contraceptive birth control, which is the only means of ensuring that love shall take control for every infant born. Contrast the coercion of motherhood by the three aggressor nations. Dr. Stopes has her preferences and gives good reasons for them. Nevertheless, the bulk of experience in municipal and voluntary contraceptive clinics is surely against her in their choice of a Dutch cap much more often than of her racial occlusive pessary; also in their satisfactory results from "Volpar" in spite of her alarm about its minimal content of Hg. Though no mention is made of a gold filigree ring as an improvement on Gräfenburg's silver one, the objections to all intra-uterine appliances are well stated. Perhaps because the book has so much personal interest, it would be spoilt for some readers by compression; but the value of recounting past controversies and ignorances becomes a little doubtful. To the majority of medical readers the possibilities of plastic repair operations, for instance, have become more important than those varieties of contraceptives designed for displaced or damaged parts. The book is published by Putnam and Co. at 15s.

Under the title *Allies of Life* the Church Missionary Society (Salisbury Square, E.C.4) publishes at 2d. a brief report of its medical work in Africa, the Near East, India, and China. Nearly 100 C.M.S. doctors and more than that number of nurses, together with their colleagues of other races (including fifty-nine doctors), are working in these fields. In Africa two pioneer efforts have actually been started since the war began—a new out-patient work in the Sokoto province of Northern Nigeria and the first C.M.S. hospital in the Yomba country, the southern portion of the vast Lagos diocese. Three C.M.S. hospitals in Palestine and one in Transjordan are doing valuable maternity and infant welfare work. In Iran the mission hospitals are increasingly appreciated by the Government. In the Moru district of the Southern Sudan 17 out-stations now bring medical facilities within reasonable reach. In India at Quetta a new hospital was opened last year, and another in Kashmir, where, Dr. Noel Fletcher remarks, osteomalacia is probably more prevalent than in any other part of India; out of 65 deliveries at the mission hospital in eight months, only 19 were normal. In China the C.M.S. hospital at Kunming, the chief Chinese city on the Burma Road, instead of being a distant outpost, is now a very important strategic mission centre. With the co-operation of the Shanghai Medical College it has become a teaching school.

Volume 13, No. 1 (June, 1941), of the *Index to the Literature of Food Investigation* has now been published by the Department of Scientific and Industrial Research at 4s. 6d. net. It is obtainable from H.M. Stationery Office, York House, Kingsway, London, W.C.2, or through any bookseller. The *Index*, compiled by Agnes E. Glennie, B.Sc., assisted by Gwen Davies, B.A., and Catherine Alexander, B.Sc., is divided into fifteen sections and deals with the different classes of meat, poultry, fish, vegetables, and dairy produce, with grain and fats, and with canning, freezing and chilling, bacteriology, mycology, and engineering.

The calendar of the Royal College of Surgeons of England 1941 (Taylor and Francis, Ltd., Red Lion Court, Fleet Street, 2s. 6d.) is necessarily stripped of much material to meet the acute shortage of paper; it has 226 pages, compared with 630 last year. All the current official information is given, but the introductory historical matter, the chronological and alphabetical register of Fellows, and the lists of Members, Licentiates in Dental Surgery, and of diplomates have been omitted. There is a roll of honour, recording the names of Fellows, Members, and holders of the L.D.S. who have been killed in action or have lost their lives from wounds or disease contracted while on active service during the present war.

Preparations and Appliances

REMOVAL OF PLASTER CASTS
A MODIFICATION OF BICKFORD'S METHOD

Major C. W. R. PRICE, R.A.M.C., writes:

About a year ago Mr. R. G. Bickford¹ described his method of removing plaster casts by incorporating piano wire in them. In practice at the Royal Devon and Exeter Hospital we found that it was a most difficult operation to hold simultaneously a limb with an unstable fracture and a springy length of wire while a plaster cast was applied. Secondly, when the time for removal came, the cut which the wire made was very narrow and a separator was required to break open the cast; impatience with the manoeuvre readily led to broken finger-nails. This second objection could be met by incorporating two lengths of wire in the cast so that "bivalving" could be carried out. However, the application of a cast having two wires involved such fantastic dexterity on the part of the operator and his assistant that it was deemed impracticable. Our third dislike was for the use of stockinet as a lining for the casts. We did write to the makers for some of the wire backed by adhesive tape which Mr. Bickford suggested as an alternative to the use of stockinet, but had adopted the method which follows long before any answer to our inquiry arrived.

FIG. 1.

FIG. 2.

Ordinary cotton tape well smeared with vaseline is laid on the skin of the limb, either in the mid-line of its anterior aspect if only one wire is to be used, or on the inner and outer aspects, or fore and aft, if two wires are to be used. The tapes are about 18 inches longer than the length of the proposed cast, so that there is about 9 inches excess at its top and bottom. The tapes readily adhere by virtue of their vaseline coating and thus do not require to be held while the plaster is being applied. When the cast has been completed, any adhesion of the tapes to the inside of the cast which the vaseline coating has failed to prevent can be broken down and the ends of the tape can then be turned back and secured by a single turn of plaster bandage (Fig. 1).

When the time comes for removal, lengths of 24-gauge piano wire can be readily pulled into position by the tapes. For the actual twisting of the wire we use two "twisters" of the type shown in the sketch (Fig. 2). These are easily made from 6-inch lengths of 1/2-inch steel tubing, and one is used to fix an end of the wire while cutting proceeds from the other end of the plaster.

DESICCANT PASTE FOR THE SKIN

British Drug Houses Ltd. have now put on the market "siccolam," a desiccant paste containing titanium dioxide, zinc oxide, and small quantities of purified silicates in a fat-free base. This preparation of metallic oxides with dehydrating and antiphlogistic effects on the skin was described by H. C. Semon and F. Herrmann in the *British Journal of Dermatology and Syphilis*, June, 1941 (p. 177). In the authors' experience "siccolam" proved, among many combinations examined for over a year, to be the most favourable application in the treatment of inflammatory dermatoses in which the use of fatty preparations was contraindicated. It is a dense creamy substance, dries rapidly when spread thinly over the lesions, and is supplied in collapsible tubes of 2 oz. and 4 oz. Other medicaments, such as tar or sulphur, can be incorporated at the physician's discretion.

PROTECTION AGAINST DIPHTHERIA

To combat the toxin which is harming a child suffering from diphtheria the physician must administer antitoxin instantly, and to this end he injects antitoxin ready-made in the horse. But the immunologist has long wished to induce the infected patient to manufacture antitoxin rapidly in his own body; thus two sources of attack would be directed against the toxin. The problem has been studied by two teams of workers in close concert with the Emergency Public Health Laboratory Service. A. W. Downie with one team studied the effects of the injection into one group of volunteers of diphtheria toxoid (A, the active immunization section), and of the simultaneous injection of diphtheria antitoxin and toxoid into a second group (A + P, active and passive immunization). F. Fulton with the other team used the A + P method in epidemics in schools. After a valuable review of the experience of previous workers it was difficult to avoid the conclusion that the antitoxin in the A + P method interferes with the primary response to the toxoid—that is, the immediate active immunization—but does not abolish the sensitizing influence which leads to the very rapid production of antitoxin when toxoid is administered at a later date. The correctness of this conclusion is the chief result of the careful research described in the pages of this and last week's issue of the *Journal*. Some 300 third-year medical and farm-training students were first Schick-tested while at the same time a sample of blood from each was taken for estimation of "natural antitoxin" content. About half of the Schick-positive individuals formed Group A and half Group A + P. In Group A (148) each received at once 0.1 c.cm. of A.P.T. (alum-precipitated toxoid) by subcutaneous injection, and those in Group A + P received the same dose of A.P.T. and also 350 to 500 units of diphtheria antitoxin into the other arm. A month later the blood of all students was titrated for antitoxin, and 0.3 c.cm. of A.P.T. was injected. From eight to twelve weeks later a third titration and a Schick test were made. Thus data were available which indicated the gradual excretion of the therapeutic diphtheria serum and the appearance of antitoxin produced in the student's body as the result of active immunization. In the A group the well-known

minimal production of antitoxin was noted after the first injection, with a rapid increase after the second injection given a month later. In from twelve to sixteen weeks from the beginning of the observations 95.7% of the A group became Schick-negative. In the A + P group the general picture was the same, with the important difference that the production of antitoxin began much later and was then slower, the early delay being due to the therapeutic serum still present in the blood. By the end of the month this had fallen to one-tenth of its initial content. The A + P group probably reached maximum production of antitoxin a month later than the A group, but the level was not much different: 90.5% became Schick-negative.

A period of low immunity occurred in the A + P group during the first month, when the therapeutic serum had disappeared from the blood and active production of antitoxin was low. This period of danger was provided for in the management of epidemics in schools by Fulton and his team. The children in the seven infected residential and non-residential schools received a dose of 500 units of antitoxin as well as 0.1 c.cm. of alum toxoid. A month later the second dose of 0.3 c.cm. of alum toxoid was injected. During the period of low protection disclosed in the research on the students the children in the schools were protected from infection, for all carriers were isolated for six weeks, when it was assumed—and correctly as the event showed—that the A + P children were immune and safe even if still infected carriers were readmitted. In the schools, with a population of about 1,500, five cases of diphtheria occurred after the campaign started, but in none of the five had the full series of injections been given. Obviously, new children entering the school must be fully immunized. The method gave excellent results in the seven epidemics in the schools, and without doubt it will be widely adopted.

The team of eight workers would have put public health administrators even more deeply in their debt if they had discussed variations of the method which may be imposed by absence of laboratory facilities or other lack. In these distressful days one may have to combat an epidemic—for example, among masses of ill-fed refugees—far indeed from laboratory aid, with only antitoxin available. Here the familiar procedure is to give 500 units of antitoxin to everyone in contact with the infected persons. Virtually complete protection is thus assured for three weeks. So far as we can learn the earliest recorded attack of proved clinical diphtheria after the giving of antitoxin occurred eighteen days later. Thereafter antitoxin would be kept in reserve ready for instant administration to anyone observed during daily inspection to be showing any symptoms suggestive of diphtheria. As the death rate from diphtheria if adequate antitoxin is given in the first twenty-four hours is almost nil, such a method gives a high degree of safety. Before Park put active immunization against diphtheria on a sound basis this method of blockage by antitoxin worked fairly

well, but recurrences after the safety period of three weeks constantly harassed the physician. If some laboratory facilities are available, what is the best evolution of this simple method of using antitoxin? We do not know if the method favoured by the late Prof. Okell¹ has been applied on a large scale: this consisted of Schick-testing and swabbing all in the infected community. It was an interesting plan. He read his Schick reactions and the swabs at twenty-four hours and immediately began active immunization of the Schick-positive, swab-negative group. The members of the group would not develop satisfactory immunity for some few weeks—a danger period. This he met by keeping antitoxin available at each daily inspection. His dangerous carriers—the Schick-negative, swab-positive group—were immediately isolated, the aim being to allow the Schick-positive group to develop some immunity free from the danger of the carrier. It is possible, even probable, that Okell would have prescribed antitoxin at the first visit if the modern digest antitoxin, with its almost complete freedom from serum reaction, had then been available.

It is difficult to estimate the danger period in the method used by Downie, Fulton, and their colleagues. Of 116 people in the A group—that is, receiving active immunization only—82% at four weeks still had 0.001 unit or less of antitoxin per c.cm. of blood, and were probably liable to infection from any chance undetected carrier. Even eight weeks after the second dose of prophylactic 29% of the A + P group showed 0.001 unit or less of antitoxin, and only 12% in the A group; presumably both were still in the danger-zone. But the proverbial pudding was good to eat, for the method gave brilliant results, and most administrators would plump for this instant insurance with antitoxin. Incidentally, the value to the medical students of this training in theoretical and practical immunology must have been indeed great.

A small comment is suggested by the recent paper of Bunch and others.² They found that almost 40% of Schick-positive medical students were sensitive to toxoid—one may say they were “pseudo-reactors.” These people would suffer severe reaction if toxoid were used in the ordinary dose, but Bunch immunized them successfully by minute doses of toxoid intracutaneously or by a long series of a dozen or more gradually increased subcutaneous doses of toxoid, starting with a 1% dilution. As Downie and his colleagues eliminated from the tables the Schick-positive students with more than 0.001 unit of antitoxin per c.cm. of blood they probably excluded many of the people acutely sensitive to toxoid but nevertheless easily immunized.³ It would have added one more to the many fascinating points in the report if the heavily “pseudo-reacting” had been dealt with in special tables.

The whole account of the research work published in our columns is a model of concerted and statistically controlled observation and its epidemiological application. The same Service will no doubt supply us with others.

CHEMOTHERAPY OF PROTOZOAL INFECTIONS

In 1937 Lourie and Yorke⁴ showed that synthalin (decane diguanidine) exerted a powerful trypanocidal action *in vitro*, a concentration of only 1 in 100 millions sufficing to destroy all the trypanosomes in a suspension of nutrient medium within twenty-four hours at 37° C. This discovery of the direct trypanocidal action of synthalin, which was of considerable academic interest in view of the fact that the chemical constitution of synthalin is essentially different from that of all known trypanocidal substances, opened up a wide field of biological and chemical inquiry. With the chemical collaboration of Dr. H. King of the National Institute of Medical Research and of Dr. Ewins of Messrs. May and Baker, a large number of guanidines, isothioureas, amidines, and amines were prepared and their trypanocidal activity examined. Certain of the aromatic diamidines produced by Ewins were found to exhibit quite remarkable trypanocidal activity, single injections of a small fraction of the tolerated doses sufficing to cure infected laboratory animals. The most active were 4:4'-diamidino-stilbene, 4:4'-diamidino-diphenoxypropane, and 4:4'-diamidino-diphenoxy-pentane. As Lourie and Yorke in 1939 found that some of these compounds also exhibited a curative action in *Babesia canis* infections of dogs, they were sent to Dr. Adler at Jerusalem with a request that he would ascertain whether they had any therapeutic action in hamsters experimentally infected with leishmaniasis; in due course Adler reported favourably. It was then decided to try the new compounds in man, and Adams and Yorke in 1939 administered diamidino-stilbene to a severe case of Indian kala-azar. The patient was apparently cured by a short course of eight daily injections of 1.0 mg. per kilo of body weight. Shortly afterwards in the same year Adler and Rachmilewitz reported the successful treatment of a woman infected with *Leishmania infantum* in Palestine, and, a year later, Adams and Yorke of a second case of Indian kala-azar.

In view of these successful preliminary results the compounds were sent to various workers in the field for more extensive clinical trial. In 1940 Napier and Sen in Calcutta tested diamidino-stilbene in eight patients with kala-azar, all of whom were apparently cured by a course of eight to twelve daily injections of 1 to 2 mg. per kilo. Kirk and Sati, in the same year, tried the compounds on a series of forty-nine patients with Sudan leishmaniasis, some of whom had relapsed after previous treatment with antimony. Forty-one of these forty-nine cases were discharged as provisionally cured; of the eight fatal cases, five of the patients were moribund when admitted to hospital and died after only a few injections, and one died after a debauch. As Kirk and Sati point out, these results compare very favourably with those hitherto obtained in the treatment of Sudan leishmaniasis with the antimonials. They write:

“The clinical picture of the uncomplicated disease is a grave one. Intractable diarrhoea, haemorrhages, and complications like cancerum oris and lobar pneumonia are frequent. Experience with antimony has shown that the

¹ Okell, C. C., Eagleston, A. J., and O'Brien, R. A., *Lancet*, 1924, 1, 593.

² *J. Immunol.*, 1940, 33, 427.

⁴ *See British Medical Journal*, 1937, 1, 612.

Indian standard treatment is inadequate in the Sudan disease, where the action of the drug is much slower. A larger total dose is usually required to effect a cure, and cases are frequently encountered which are completely resistant to any form of antimony treatment. Moreover, Sudanese kala-azar patients are very sensitive to the toxic effects of antimony, and the early attempts to treat the Sudan disease with this drug along the lines advocated in India led only to a series of disasters, which Archibald recognized as attributable to the drug rather than to the disease."

In view of the relatively great difficulty which has been experienced in curing Mediterranean and Sudan leishmaniasis with antimonials, it is not surprising that both Adler and Kirk found that much larger quantities of the diamidines were required in this form of leishmaniasis than in Indian kala-azar. The size of the individual dose given varied between 1.0 and 2.5 mg. per kilo of body weight, and apparently at least thirty injections were necessary to produce a cure. It is as yet too early to decide what value these compounds have in the therapy of human trypanosomiasis. Reports so far available indicate that they produce rapid peripheral sterilization, and that they cure early cases. Diamidino-stilbene, which has hitherto been mostly used in cases of sleeping sickness, apparently fails to cure cases in a late stage with pronounced changes in the spinal fluid; but preliminary reports received from Lourie in Sierra Leone suggest that diamidino-diphenoxy-pentane and diamidino-diphenoxy-propane may prove more valuable than diamidino-stilbene in such cases. The therapeutic activity of these compounds in dogs infected with *Babesia canis* has been examined in Kenya and Uganda. In 1941 Daubney and Hudson in Kenya treated sixteen infected dogs—most of them pure bred—with diamidino-stilbene, and cured fourteen with a single dose; two advanced cases, one of which was moribund when treated, were fatal. In the same year Carmichael and Fiennes, in Uganda, cured 102 of 116 infected dogs with a single dose of diamidino-diphenoxy-propane; ten relapsed, but were cured with a second dose, and four died. Carmichael and Fiennes conclude that this new compound has proved the most valuable drug they have so far encountered in the treatment of tick fever (*Babesia canis*) in dogs.

WAR PRODUCTION AND HEALTH

Because of the increasing magnitude of the national effort we are now as a nation faced with production problems which are unparalleled in history. Not the least of these problems is that of absenteeism. It is difficult for medical observers to know how much of absenteeism is due to ill-health, and therefore to what extent ill-health is responsible for the falling off in factory output which is reported to have taken place recently. In a few industries accurate statistics are available, but only in a proportion of these is the sickness record of the individual and his occupational group analysed critically with a view to the employment of preventive measures. Until we have a compulsory method of notifying factory absenteeism caused by sickness, just as it is now compulsory for employers to notify to the Factory Department accident

cases that cause a loss of three or more working days, we cannot as a profession see the problem in its true perspective or give industry our optimum assistance. Prof. John Ryle has recently commented forcibly on the need for further inquiries into the human factor in its relation to war production "if a true assessment of causes and effects is to be reached." The report of the B.M.A. on industrial medicine, now published and summarized elsewhere in this issue, backs up Prof. Ryle's appeal and emphasizes the need for both research and education in connexion with industrial health. These and other problems in industrial medicine are ably dealt with by Dr. Donald Stewart in an article at page 762.

The time has never been less propitious for resting on the laurels of research carried out during the last war or in times of peace. The work of the Industrial Health Research Board, which was based on accurate facts and observations at the time, must go on and must take cognizance of present-day factors, and in particular of the importance of propaganda. Factory accidents are increasing; the black-out has its own peculiar problems; the importation of labour to many industrial centres presents medical aspects of the greatest significance; and the ever-increasing number of women workers entering factories has become associated with many health problems, not the least of which is the possible increase in tuberculosis. Again, some authoritative statement is required on the supposed efficacy of vitamin therapy, ultra-violet therapy, and vaccination in the prevention of the common cold, generally accepted as the chief cause of absence from work. Some statement, if it can be given, is wanted now because both workers and managements are demanding guidance from the medical profession on the institution of positive preventive measures, and in the absence of this they are often proceeding on their own responsibility on "hit-or-miss" lines and without medical advice.

As a result of the Factories (Medical and Welfare Services) Order of 1940 the number of medical officers in factories has so increased that our profession is now well represented within the factory walls and ready to help. But how? The majority of these doctors have had but little training in their subject. Many of those newly appointed have had to find their own feet and work out their own salvation. And in these days of crisis how wasteful this has been! The facilities for education and practical help have been limited to sporadic week-end courses at three provincial universities—Birmingham, Manchester, and Sheffield—although there never was a better case for continuous assistance, possibly at week-ends, both in these centres and in London. The factory doctor wants advice and help from the best brains in the profession, and he wants it now. He needs it not so much on the treatment of injuries and the organization of casualty services—for which at least he has had some training—but rather in relation to the wider problems of the prevention of accidents and sickness among his workers, and to the need for linking up medicine with the social requirements of the community, which is the true basis for the maintenance of health in industry.

THE STIMULANT ACTION OF IRON

Whatever may happen in animals, it is generally agreed that the normal human being absorbs large quantities of medicinal iron, even when all precautions have previously been taken to ensure adequacy of the reserves; two directly contradictory papers dealing with this point were presented at the last meeting of the American Society for Clinical Investigation.^{1,2} During the last decade it has been assumed that iron acts as a nutritional element rather than as a drug. Helen Mackay,³ at the beginning of this phase, had shown that the haemoglobin levels of artificially fed babies treated with iron surpassed those of breast-fed babies, and she had used the higher figures in the construction of a standard normal haemoglobin curve in infancy. In 1936 Widdowson and McCance⁴ gave iron to a normal group of men and women and observed their haemoglobin levels. The women's haemoglobin tended to rise and approach the men's level; the men's haemoglobin did not change. This might have suggested that women normally have a mild but pathological anaemia. In 1938 Sankaran and Rajagopal⁵ confirmed the fact that the haemoglobin content of the blood in healthy young females could be raised by the daily administration of ferrous sulphate, but they found that the haemoglobin returned to the original level when the iron was discontinued. Miss Widdowson⁶ then showed that the administration of iron in therapeutic doses to pregnant women converted into a rise the fall in haemoglobin which was then in progress. After the administration of iron had been discontinued the haemoglobin fell once more, and at about the same rate as if iron had not been administered.

These observations have very seriously upset the view that the maximum haemoglobin levels which can be attained by giving iron to pregnant and non-pregnant females and to infants really are optimum or physiological levels. They are probably just as abnormal as complete saturation with vitamin C. Miss Widdowson suggested that one of the factors concerned in the level of haemoglobin in circulation is the amount of iron in the plasma; the administration of iron temporarily raises the level of plasma iron, which stimulates the marrow to greater activity. Such a stimulus is from the evolutionary point of view a highly abnormal one, as the intake of iron in the food is never such as to cause comparable rises in the plasma iron. The subject has been carried a stage further by Fowler and Barer,⁷ who show that when medicinal iron is administered to normal subjects there is a gradual increase in the blood haemoglobin which reaches a peak in about ten to twelve weeks and then gradually falls to the pre-treatment level even though the administration of iron is continued. This is true whether the initial haemoglobin level was low normal or high normal, though in the latter the response is less marked. The work was apparently done on both males and females, but the effects are more noticeable in females, inasmuch as their haemoglobin level is more often on the low side of normal. A similar supernormal peak and subsequent fall to normal levels is observed during the successful treatment of hypochromic anaemia. What, then, is the student of nutrition to regard as the normal level of haemoglobin? It is certainly not a uniform level but a rather broad zone with considerable individual, sex, and age variations. It is the level found in a group of healthy people living on a good

diet. The mere fact that a haemoglobin level can be temporarily raised by iron medication is no proof that it was initially abnormal, and unless we are to regard infancy and pregnancy as morbid states we must accept the view that the level of haemoglobin is normally lower at these times, perhaps for some good reason. In pregnancy, at all events, the circulation is much altered, and it may well be that the tissue tension of oxygen remains normal in spite of the depression in haemoglobin.

OCCUPATIONAL ACNE

Among the manifold skin lesions met with in industry, and clearly attributable to chemical causes, acne is relatively uncommon. So-called "oil acne" is not, we believe, the result of chemical injury. Where acne is already present a superimposed chemical dermatitis does not appear to aggravate the condition: the distribution is, in general, different, and the dermatitis may clear up, leaving the acne to pursue its course more or less uninterruptedly. While many hold that sufferers from acne are likely to have an increased tendency to industrial dermatitis, this probably applies only to certain exposures, and may, in the last analysis, be traceable to the coexistence of dirt and seborrhoea rather than to the acne. Typical acne, with its characteristic lesion, has for long been known as an industrial disease and referred to variously as "chlor-acne," and by the Germans as *Pernakrankheit* from its association with exposure to the fumes of perchloronaphthalenes. Inorganic chlorine compounds have been blamed as well as chlorine itself. A. Thelwall Jones, who has had much practical experience, does not believe⁸ in the association of chlorine with so-called chlor-acne. Occupational acne among workers engaged in the manufacture of a host of chlorinated organic compounds is a disease almost unknown in one large firm in this country. Many of these compounds give rise to severe dermatitis, but acne does not occur. Many reports, however, have appeared on the acne which results from exposure to the fumes of chlorinated naphthalenes and chlorinated diphenyl, and Jones describes his own observations of occupational acne among workers engaged in the manufacture of these compounds. Alkyl derivatives of naphthalene with chlorine substituted in the side chain readily give rise to dermatitis, but never of the acneiform type. Thus there seems to be something very special about the action of chlorinated naphthalenes and chlorinated diphenyl. The view of Teleky in 1927 was that the effect on the skin was proportional to the chlorine content, and that much improvement was attainable if the chlorine content were diminished from 30% to 8%, the loosely bound chlorine being removed.

There are several points of great interest in these cases of occupational acne, and they are carefully described by Jones. There is a long latent period between the beginning of exposure to the fumes of these compounds and the appearance of the lesions; this varied in Jones's series from one month to two years, with an average of seven months. After proper treatment the acne may recur even after removal from exposure, and final disappearance may be delayed for anything up to two years or more, particularly if infection has become superimposed. The lesions in Jones's cases were most commonly on the face and below the ears; a few occurred on the forehead, but the nose and mid-line of the face were spared; in severe cases the neck, chest, upper abdomen, arms and extensor surfaces of the forearms, the back, thighs, and buttocks may also be affected. As distinct from acne vulgaris there is in this condition a very large number of fine blackheads and

the eyes without the greasiness of the skin found in the former. Areas of skin where friction is likely to arise or which are not washed regularly are particularly susceptible; dirt in general is a predisposing factor, and Jones's worst cases occurred in workers of uncleanly habits. He suggests that the mechanism of production depends upon the solution of the chlorinated bodies in sebum; when not washed away the compounds irritate the sebaceous glands, stimulate the local growth of the stratum corneum and the secretion of sebaceous matter, and thus lead to blockage of the follicle with possible secondary infection. As opposed to the view of several other observers (Macleod among others) that chlor-acne results from absorption of the chemical through the respiratory and digestive tracts, with subsequent excretion through the pilo-sebaceous follicle, Jones believes that it is due to local external irritation, particularly as the effects are local and leave the rest of the skin untouched. Attempts to demonstrate an attack on the skin by direct application of the vapour of molten chlor-naphthalenes to human skin (back) were, however, negative. In view of the recent addition of poisoning by chlor-naphthalenes to the schedule of industrial diseases, it is interesting that Jones found no cases with obvious signs of hepatic disease. Nevertheless there can be no doubt, on the grounds both of animal experiment and of several human cases in the literature, that excessive exposure to these fumes leads to necrosis of the liver.

The recommendations the author gives for protection of workers engaged in the manufacture of these compounds follow well-recognized but often neglected principles. The trouble lies in part in the lack of co-operation and understanding by the workers. Jones's points are worth recording: (1) The worker must be taught the nature and course of the condition. (2) Overalls must be provided—light-coloured, highly starched, closely woven, full-length sleeves, and a proper neck. Full-length underwear should be laundered at least once a week. (3) There should be adequate locker accommodation. (4) The worker should avoid touching the body and the face with his hands; rags should not be used for wiping the nose or face. Washing should be enforced before meals, and no one should eat while at work. (5) Adolescents should not be employed, nor should men with seborrhoea or acne. (6) Frequent medical inspection is necessary, and early cases should be removed from further exposure. (7) No other work should be done which entails much sweating. No reliance can be placed upon "protective" creams in this hazard; the whole emphasis is on cleanliness and medical supervision.

A NEW TEST FOR INFLUENZA VIRUSES AND THEIR IMMUNE BODIES

The unexpectedness of research is one of its charms: the most unlooked-for things turn up. Hirst¹ was removing influenza A virus from developing chick embryos when he noticed that the red cells of the infected chick, coming from ruptured vessels, were agglutinated in the allantoic fluid. Since red cells in the allantoic fluid of chick embryos inoculated with sterile materials did not agglutinate at all, it seemed that this agglutination phenomenon might be the result of infection with influenza virus in the chick: such in fact proved to be the case. It is quite an easy thing to demonstrate the agglutination phenomenon in the infected chick embryo. The egg shell is opened over the air sac, the outer chorio-allantoic membrane is torn away, and several large blood vessels are purposely ruptured. Fifteen to thirty seconds are allowed for the embryo to bleed into the allantoic fluid before the contents of the

allantoic sac are emptied into a Petri dish. If the embryo has been infected with the influenza virus macroscopic agglutination of the red cells occurs within fifteen to thirty seconds in the Petri dish. If agglutination does not appear promptly it usually does not occur at all, and the differentiation between positive and negative eggs is thus rendered easy.

By using this agglutination phenomenon as an index of infection it was found possible to carry out virus titrations and serum neutralization tests. One-tenth c.c.m. of the material is inoculated into the allantoic sac of 11-day-old embryos, which are allowed to incubate for two days; the eggs are then opened and positive and negative reactions are recorded. The end-points in serum and virus titrations are as sharp as those obtained in the mouse-protection test; agglutination tests work equally well with strains of influenza A and B virus and swine influenza virus, the specificity of each strain being easily demonstrated. A neutralization test with acute and convalescent serum from a case of influenza A demonstrated a rise in antibody titre in the convalescent serum which was consistent with the rise obtained in similar tests in mice. A test-tube agglutination reaction has also been elaborated. When infected allantoic fluid, either fresh or stored at -72°C ., from which the red cells have been removed by low-speed centrifugation, is mixed with washed red cells from the normal developed chick agglutination occurs. The *in vitro* agglutination phenomenon is somewhat slower than that carried out in the egg, as it takes from five to twenty minutes to get a reading. The red cells sediment rapidly and form a characteristic ragged granular pattern on the bottom of the tube. When an influenza antiserum is added, in dilutions as high as 1 in 1,024, to the allantoic fluid infected with the homologous virus, the agglutination phenomenon is inhibited. The agglutination-inhibiting substance in human sera parallels the neutralizing antibody titre more closely than the complement-fixing titre. At present neither the mechanism of the agglutination phenomenon nor its specificity for influenza virus infections is well understood, but it seems that this test may well replace the mouse-protection test for determining serum neutralizing antibodies.

Dame Edith Mary Brown, M.D., Principal of the Women's Christian Medical College, Ludhiana, Punjab, has now completed fifty years of devoted work in alleviating the physical sufferings of Indian women by the provision of qualified Indian women doctors, nurses, and midwives. She first landed in Bombay on November 9, 1891, and with a gift of £50 from a Bristol lady she rented an old school house at Ludhiana, using a little hospital near by for the clinical teaching of her early students. From this small beginning the first medical school for women in India has developed into an institution where for years past there has been an average of 300 Indian women students in the medical, nursing, pharmacy, and maternity schools, with classrooms, laboratories, and a hospital of 260 beds. A tribute to Dame Edith Brown's pioneer work in the Punjab appeared in the *Times Educational Supplement* of November 15. A jubilee thanksgiving fund has been opened at the London office of the College, 39, Victoria Street, S.W.1.

Prof. F. C. Bartlett, F.R.S., who holds the Chair of Experimental Psychology in the University of Cambridge, has been appointed a member of the Medical Research Council in the vacancy caused by the death last July of Prof. A. J. Clark, F.R.S.

CLINICAL TEACHING

BY

Professor ARNOLD LOEWENSTEIN, M.D. Prague

(From the Tennent Institute of Ophthalmology, University of Glasgow)

Generally speaking, one assumes that scientific knowledge is handed down by means of the written word. Advances are communicated to the journals, from these into books, and to students in the form of textbooks. This is certainly so in the exact natural sciences—physics, chemistry, botany, and the others; but there are limitations to this process. In individual schools attention is devoted to certain specialties; views are taught which differ from the opinions in other institutes, and special techniques are cultivated. Many such schools, like those of Karrer, Euler (vitamin chemistry), Einstein (theoretical physics), Mme Curie, Ramsay, and Rutherford (radiant energy), remain unique; but these are exceptional. In the main there is a continuity of teaching, and a new teacher can, without difficulty, proceed from the point arrived at by his predecessor.

It is quite otherwise in *clinical* instruction—not so pronounced with undergraduate as with postgraduate teaching. Personal methods, often unpublished, occupy an important position and have to be passed on to the pupil in connexion with appropriate cases. This applies to the choice of method in investigation and treatment, and to the determination of indications for certain operative procedures, and, last but not least, to operative technique.

Individuality of the Teacher

The choice of particular specialties within a specialty is very characteristic. In this matter the individuality of the teacher plays its part. The wide knowledge of the master, which even the most careful study of the literature cannot replace, saves the student from many handicaps which otherwise would be unavoidable. The daily instruction based on the clinical cases gives the junior a stimulus to pursue new investigations with results which are a source of pride to the master as great as if the work were his own. It was in this way that the large clinical schools came into being, such as the surgical clinic of Billroth in Vienna and of Czerny in Heidelberg, the ophthalmological school of Fuchs in Vienna and of Axenfeld in Freiburg, Cushing's neurosurgical clinic in Boston, the neurological and psychiatric schools of Paris and Rome, and others. The unique character of the clinical work, of the teaching, of operative technique, and of investigation is absorbed almost unconsciously by the student. He receives the stamp of the school, and is initiated into many unpublished details through verbal tradition. Although each member of the school is concerned with his own line of investigation, all work together towards a common end.

It is obvious that this system has its drawbacks. A chief who has a strong individuality may tend to overpower his juniors; independent pupils often become antagonistic to their teacher, while the less independent lose the rest of their individuality; but there is no doubt the positive side of this kind of teaching prevails.

In this country what impresses a clinical teacher from Central Europe is this cult of individuality, and, as a corollary, the absence of "schools" in the explained sense of the word. All prominent clinical scientists here are individual workers, not standing on the shoulders of predecessors and carrying forward their work. They are like mountains rising out of the plain without foot-hills! It is difficult to understand how these prominent personalities could perform their great work alone, without any help.

No doubt this has its advantages; for the need to overcome obstacles is a valuable discipline, and it ensures that only those really capable reach their goal and that all competitors are eliminated. On the other hand, the system involves a certain dissipation of energy, since each investigator has to make a fresh

beginning, lacking the support of his teacher's experience, as one removes the stones from his path. The logical result is that the "middle class" of science, who form the backbone of scientific investigation everywhere throughout the world, is eliminated.

It seems to me unfortunate that the great mass of first-class ability which I have met with in this country is thus deprived of the opportunity for the easy training in clinical science of which it is capable. The large numbers of talented, interested, and enthusiastic young men whom I have met here present a guarantee of capacity for first-rate achievement. Their independence of thought and interest in new ideas would be the joy of any academic teacher. It seems to me that in this we may see an important principle of the British educational system, which aims rather at the development of individual character than at the accumulation of knowledge.

I have found the same characteristics in the undergraduates, whose powers of judgment and understanding are well above the average of those of Central Europe. The questions they ask in the course of their instruction show a gratifyingly acute grasp of essentials. But in this country medical education is placed far more in the hands of the young men unaided and uncouraged. They must take the trouble themselves to get up the necessary information. There is no doubt that they have a much harder time than their Continental comrades. As the number of paid assistants here is very few, most of the young men willing to learn more have to strive for their own living. Usually they serve their time as general practitioners. They gain their education in the chosen specialized subject by great sacrifice, by means of serving in their free hours as voluntary assistants in a clinic. They often arrive tired and worried, as they have only a short time at their disposal. The senior surgeon is so busy running his big clinic that he has very little opportunity for discussion and teaching, even with the best will to do so. I have often admired the idealism of these young people to be able thus to qualify themselves in spite of unfavourable conditions.

Choice of Clinical Teachers

For those of us who have been teachers in the universities of Central Europe it is particularly difficult to understand that the medical faculty of the university has hardly any control, for instance, in the choice of the majority of clinical teachers, except in the case of professors, and that the office of lecturer is often attached to that of physician and surgeon in a hospital in whose appointments the university has little influence. On further reflection, this also is seen to have a certain advantage, for the head of a clinic can easily become an absolute dictator when all the appointments to his special department are entrusted to him. At the same time it is risky to hand over the duty of instruction to any practitioner, however experienced, without regard to his capacity as a teacher.

If it is difficult to find a clinical teacher who possesses didactic, clinical, operative, and scientific ability in equal degrees, still more is it unfair to expect all this of a very busy practitioner, even though he lose no income. The practitioner who has to move from one job to another cannot have time for the necessary careful preparation of lectures even if he were well supplied with teaching material, which is not easily available. It will be especially unsatisfactory in the case of postgraduate instruction, where the effect of growing competition is great.

Clinical teaching as a whole-time job as we see it in many parts of the U.S.A., and also as adopted voluntarily by some outstanding individual and idealistic teachers in this country, is the only solution of the difficulty. Only by an adequate salary and pension provision can the whole-time teacher be freed from the burden of private practice with its competition, to find time for his teaching and for scientific work without care and without anxiety for the future.

The choice of full-time teachers must be very carefully made, and "inbreeding" must be avoided. Experience shows that the appointment of those educated and qualified in the same way does not bring the necessary fresh blood. I would strongly support the plan whereby clinical university chairs should not be restricted to citizens of these islands. Young American teachers, for instance, could bring new ideas and fresh opinions which would be welcomed here.

Chairs for Special Subjects

Only on historical grounds can we understand how it comes about that diseases of the skin, eye, nose, and ear, and the diseases of children are taught often in second-rate clinics with very limited teaching periods and no control by examination. These specialties have assumed their present significance only within the last few decades; their social importance has enormously increased, and the methods involved in their investigation and treatment have become too complicated to be taught, even sufficiently for the general practitioner, in the short time here allotted to them—namely, one term of ten weeks, three hours a week—while 300 hours of ophthalmology are compulsory at most of the Continental universities. The fact that there is only one professor of ophthalmology in the British Empire is scarcely credible.

But the authority of this professor is no greater than that of a lecturer. The foundation of similar chairs for such special subjects as diseases of the eye, nose and ear, children, skin, and neurology, with endowed clinics and with the power of examination, is a necessity for all universities. Whether private charity can achieve such great expenditure I naturally cannot say, but teaching and the care of the sick should not need to depend on whether a rich man will leave the necessary money in his will.

Independence of the Universities

The absolute independence of the universities in all directions from Government and politics is one of the greatest stimuli. We have learnt with astonishment to what straits freedom of teaching and learning can be brought by the uncontrolled dominance of absolutist States. That is the basic idea which has led to the independence of the universities in this country. A glance at conditions in Europe shows us clearly enough that domination of the universities by the State is not an ideal for which to strive.

But in a democratic State it is easy to have security of the universities from excessive Government control, as we see in the exemplary constitution which the universities of my country, Czechoslovakia, owe to Masaryk, the first President of the republic. Even the high schools are national, but the Government had merely the power to confirm appointments, and every other form of interference is rendered impossible by law. Thus the remarkable condition arose that the German University of Prague, the high school of a minority, was the last free and independent German university at a time when all others except those of Switzerland were under dictatorial control.

In Great Britain, this democratic country of individualities, there would be little danger to freedom in teaching and learning, even under financial dependence on the State.

An Urgent Aim

The future of the nation lies with the youth. That which life has taught us, our knowledge, is a loan only, and we have to pass it on to the next generation after it has been increased by the result of our research work. All depends on the education of the young medical men, to whom will be entrusted the health of the nation. To educate these promising young men in the most skilful and efficacious manner and to remove the whole affair from the atmosphere of financial anxiety is the most urgent aim of the medical schools, universities, and Government.

The first thing to have in view is the instruction of the coming academic teachers responsible for the education of the future generation of physicians. It is more than careless to leave the election of these to chance, as happens everywhere (I am not informed how it is done in Soviet Russia), instead of seeking the most suitable. The best of all the medical pupils must be chosen according to their creative gifts, to their knowledge and enthusiasm, and they should get scholarships and paid assistantships to provide their livelihood, just as lectureships are available in physics, chemistry, etc. The young clinician has to dedicate himself to full-time learning, research, and teaching. During this time of apprenticeship at the clinic the young scientist requires study-leave to take up special methods in other clinics. This study-leave is one of the most important factors for the furtherance of development. This is usually very difficult to arrange later on, owing to the calls of private practice and family life. The best time for such a study-leave is towards the end of the

assistantship, when four to five years of careful learning have made the young man into a well-informed clinician who has probably by this time published some results of his research work. It is a disadvantage that the teachers and specialists in this country often receive all their education and pursue their calling in *one centre*. The danger of "inbreeding" can be avoided only by the interchange of clinicians and teachers between the different schools and universities of this country and abroad.

The Specialist

At least three to four years' intensive full-time training should be required before a medical man is granted the title of specialist. I doubt if an examination limited to one or two days is enough to convince the examining board that the life and health of thousands can be entrusted to the candidate.

The specialist must progress with his profession: he learns the developments in his science by reading the medical journals, but personal contact with modern clinics is necessary. The best results have been obtained in the so-called "postgraduate courses" for specialists. One well-known clinician is deputed to prepare such a course, and he enlists the co-operation of other colleagues—specialists in related subjects. All advances in this specialty—in diagnosis, histology, chemistry, pathology, optics, in operations and treatment—are carefully gathered and concentrated into a week's teaching. Very often quite old senior surgeons sit enthusiastically at the feet of young teachers. The debates after the meetings are really delightful and are highly appreciated. These postgraduate courses in Continental schools, as well as in the U.S.A., where they have been highly developed during the last few years, are so greatly valued that usually not more than one-quarter of the applicants can be accommodated.

Excellent postgraduate teachers could be found in this country very easily. The specialists of the British Empire and of America would be the enthusiastic audience. There could easily be created medical centres greater than all previous ones. It is only a question of organization.

The education of the medical man is a matter concerning the whole nation as a unit, as well as concerning individuals. The national prosperity very often depends on it. The labour expended on this task is a fruitful one. It must follow the development of science closely, without regard to historical constraint.

Conclusion

I have attempted here to explain why Great Britain does not enjoy the world-wide importance in medical science which she should have in view of the great intelligence of her people. This is, in the first place, due to the lack of financial security for teachers which compels many able and outstanding men to waste their energy in private practice, and to the insufficient opportunities of specialist training, for young and promising medical men, who find themselves forced to concentrate their energies on earning a livelihood instead of devoting themselves to study, investigation, and research. I have repeatedly had occasion to learn that to follow the second of these courses is their real desire.

From all sides I hear of the longing for reforms, which are certainly on the way. The sooner they come the sooner will this country, so rich in creative talent, take the place in clinical medicine which the ability of its people entitles it to claim.

For perhaps the first time in German hospitals an attempt has been made in a reserve hospital to utilize sick and wounded soldiers for silkworm culture. The arrangements which had already been made in a military tuberculosis hospital served as a basis. The soldiers were set to work on the cultivation of mulberry trees, and followed on with the breeding of silkworms. The care of silkworms, which is easily learnt, was carried out under the instruction of experienced doctors and nurses. It is necessary, as in the case of all occupational therapy, that the doctor himself should take part in the work.

THE GEOGRAPHICAL DISTRIBUTION OF GASTRIC AND DUODENAL ULCERS IN THE BRITISH ISLES

WITH NOTES ON THE AETIOLOGY OF PEPTIC ULCER

BY

B. M. NICOL, M.B., Ch.B.

Major, R.A.M.C.; late Assistant in Medicine, Aberdeen University; Carnegie Teaching Fellow, Edinburgh University

At a meeting of the Section of Medicine of the Royal Society of Medicine Sir Arthur Hurst (1941) mentioned some remarkable differences between the incidence of peptic ulcer in soldiers and in civilians. In private practice duodenal ulcer was about four times as frequent as gastric ulcer, though in hospital practice this did not obtain (in three of the large London hospitals the statistics, both clinical and post mortem, over a good many years showed an equal incidence of gastric and duodenal cases). In the Army, apparently, duodenal ulcers were in the large majority.

In view of the increasing importance of peptic ulceration in both the Forces and the civilian population, the following investigation carried out in Aberdeen in 1938 and 1939 may be of interest.

Relative Incidence of Duodenal and Gastric Ulcer in the British Isles

During a "follow-up" investigation of 435 patients admitted to Aberdeen Royal Infirmary suffering from proved peptic ulceration the relative incidence of duodenal to gastric ulcers was found to be 6.8 to 1. When these figures were compared with others previously published it was found that the relative incidence of duodenal and gastric ulcer apparently varied slightly throughout the world, but very remarkably in the British Isles. The collected figures are shown in Table I. Although the series are not strictly comparable, some being from medical, others from surgical, wards, the findings in the different

districts are constant enough to be considered significant. Two interesting facts have been noted: (a) the apparently high incidence of gastric ulcer in the hospital patients in London; and (b) the very constant sex incidence of peptic ulcer throughout the world, whatever the relative incidence of duodenal and gastric ulcers in a given area.

(a) The relative incidence of duodenal and gastric ulcers in hospital patients varies considerably between London and the Provinces. The ratio of duodenal to gastric ulcers (male and female) in London is 1 to 1, in Leeds 2.8 to 1, and in Scotland from 6.8 to 8 to 1. Luff (1929), reporting the collective investigation from the whole of England, found the ratio to be 1.8 to 1, intermediate between the London and Leeds figures. Table Ia shows that the incidence of duodenal and gastric ulcers is very constant in private patients, both in America and in the British Isles, although the figures from America show a slightly lower ratio of duodenal ulceration to gastric ulceration. In Britain it appears that gastric ulcer is less common in the north than in the south, and, in particular, London seems to have a very high proportion of gastric ulcers (Table II).

TABLE II.—Showing the High Proportion of Gastric Ulcer in London

London ..	1,667	1,836
Leeds ..	927	327
Scotland ..	1,030	154

For purposes of comparison with figures being collected from the Forces, the numbers of males in these areas are shown separately in Table III. The incidence of duodenal

was 9.1 to 1. Payne and Newman (1940) found a ratio of 4.2 duodenal ulcers to 1 gastric ulcer among 227 proved cases from the Forces, and Graham and Kerr (1941) reported that the ratio of duodenal to gastric ulcers among 158 serving men was 5.9 to 1. The great excess of duodenal ulcer in the Forces compared with gastric ulcer is similar to that found all over the world, excluding London.

(b) The sex incidence of peptic ulceration in both private and hospital practice is remarkably constant throughout Britain and the world generally, affecting males three times as frequently as females. In districts where the incidence of duodenal ulcer is very much higher than gastric ulcer the predominance of males is not quite so great, owing to a relative increase in the number of females suffering from duodenal ulcer (Table IV). Table I shows that this sex

incidence of about three males to one female is very constant throughout the world. Certain differences in the aetiology of duodenal ulcer and gastric ulcer have been observed, and are here reported, as they appear to have a bearing on the problems of the geographical distribution and sex incidence.

Differences in Aetiology of Duodenal and Gastric Ulcers

Age Incidence.—The age of onset of symptoms in the majority of cases of duodenal ulcer is between 20 and 30 years. In gastric ulcer the curve for the age of onset is spread uniformly throughout life between the third and sixth decades, the maximum incidence being distributed evenly, without the marked peak between 20 and 30 found for duodenal ulcer (see Chart).

Chart showing percentage of all duodenal and gastric ulcers in 10-year groups. (Age at onset of symptoms.)

Family History.—In cases of duodenal ulcer a family history of peptic ulceration has been found more than twice as often as for gastric ulcer. In a control series of 300 cases of acute and chronic appendicitis a family history of peptic ulceration has been found with the same frequency as in the gastric ulcer patients of this series (Table V). The

Duodenal ulcer	76	292	21
Gastric ulcer	5	49	10
Appendicitis	29	271	10

larger number of positive family histories among the duodenal cases has been shown to be statistically significant.

Factors associated with the Onset of Relapse of Duodenal and Gastric Ulcers.—Davies and Wilson (1937) pointed out the very frequent occurrence of external events causing mental or psychological strain shortly before the onset of dyspepsia in peptic ulcer patients. They found that such events were present in 84% of their cases. Using their methods of investigation in 232 patients of this series (187 duodenal and 45 gastric ulcers) external events of a nature disturbing to the patient have been found on 160 occasions (Table VI). These events have been classified

TABLE VI.—External Factors

	Duodenal	Gastric	Total
Mental Strain:			
Worry—			
Family troubles	22	2	24
Finance	21	—	21
Employment	19	6	25

under two headings, mental and physical. An external factor was thus found in 70% of patients, the strain being mainly mental or psycho-physiological in 43% and mainly physical in 27%. The factors most often associated with the onset or relapse of symptoms are worry and dietetic errors. There is a marked difference in the incidence of gastric and duodenal ulcers due to these two factors: mental strain is more commonly associated with the onset or relapse of duodenal ulcers; physical factors, mainly acting through irritation of the gastric mucous membrane, are more frequently associated with the onset of gastric ulcers. Worry or overwork often leads to faulty dietetic habits, and many nervous or irritable patients blame dyspepsia as the cause of their irritability. Overlapping of mental and physical factors is bound to occur, but among the patients examined and classified in Table VI one predominant factor could always be found. The larger number of duodenal ulcer cases falling in the mental strain group is statistically significant.

Ulceration of both the stomach and the duodenum was found in 13 patients of the Aberdeen series (not included in Table VI). Among these patients only 2 had associated mental and physical strain factors, both of which could be classed as important; in 5 the external factor was physical in type, in 2 mental, and in 4 no external factor of disturbing significance to the patient was discovered.

Discussion

In view of (1) the variation in relative incidence of duodenal ulcer and gastric ulcer in Britain and throughout the world, and (2) the differences noted in the aetiology of the two forms of ulcer, the following hypothesis is advanced.

Two different sets of factors are at work in the causation of peptic ulceration. These can be called "D" factors, leading to duodenal ulcer, and "G" factors, resulting in gastric ulcer. The "D" factors are usually inherited, but may be aggravated or even originated by mental stress and anxiety. They are active most frequently in the third decade of life, and appear to be psycho-physiological in character. The "G" factors, on the other hand, are not inherited, occur throughout life more or less uniformly from the second to the sixth decade, and lead to local

trauma of the gastric mucosa. The sum of the "D" and "G" factors causes peptic ulceration approximately three times as often in males as in females.

Without detailed knowledge of the environmental conditions and habits, both mental and dietetic, of the general population of this country, it is impossible to test this hypothesis satisfactorily, but arguments can be brought forward to support it.

It is probable that faulty habits of eating or occasional excesses, resulting in trauma to the gastric mucosa, occur throughout life and are not mainly concentrated in the third decade. Upper respiratory or other infections at a distance from the stomach but which may result in acute focal gastritis of a blood-borne type, and acute febrile illnesses, are also found throughout life. During the decade in which the majority of cases of duodenal ulcer start—i.e., 20 to 30—the individual is faced with the issues of success or failure in his or her profession, and has often assumed responsibilities which strain both his ability and his financial resources. Later, as security becomes more certain and responsibility is less of a strain upon the individual the incidence of duodenal ulcer falls.

If it be assumed that the "D" factors are chiefly psycho-physiological in character and the "G" factors act mainly by irritating the gastric mucous membrane locally, an explanation is supplied for the greater incidence of both types of ulcers in males. Worries of all sorts, errors of diet or excesses of eating and drinking, and irregularity in meal hours are all much more apt to occur in males than in females. The incidence of peptic ulcer, particularly of duodenal ulcer, has increased in females since the beginning of the century in common with the incidence of peptic ulcer as a whole (Wilkie, 1927), and this may be explained by the increased responsibilities assumed by and delegated to the female sex. The swing from a preponderance of gastric ulcers to a preponderance of duodenal ulcers that has occurred since the beginning of the twentieth century is due to (a) improved methods of diagnosis, (b) an increase of "D" factors (hurry, anxiety, competitive strain, etc.) which has occurred since the beginning of the present century, and (c) a reduction in "G" factors owing to an improvement in the nation's diet and a spread of knowledge regarding physiological methods of eating.

London is the only big city in the world in which an equal number of duodenal and gastric ulcer patients are treated in hospital. There are two possible explanations of the London figures: (1) that the population of London has dietetic habits that differ from those of the populations of other cities; or (2) that the percentage of patients in London suffering from duodenal ulcer who are treated as in-patients in hospital, and not as out-patients or as private patients in their homes by general practitioners, is less than in other cities all over the world.

Since the figures for the incidence of duodenal ulcers and gastric ulcers in London differ so materially from those available from other large cities all over the world, it is suggested that the second explanation given above is the correct one.

It is generally believed that peptic digestion of a devitalized area of gastric or duodenal mucous membrane is the ultimate factor in the production of peptic ulceration. The cause of this devitalization is not known for certain, and no doubt many factors play a part. Cushing (1932) and Necheles *et al.* (1938) have noted an association between nervous lesions or disturbances and peptic ulcer. In view of the above-noted aetiological importance of external factors, chiefly psycho-physiological disturbances ("D" factors), in the production of duodenal ulceration, and local

trauma to the gastric mucous membrane ("G" factors) in gastric ulceration, it is suggested that the cause of the devitalization is mainly psycho-physiological in duodenal ulcers and traumatic in the case of gastric ulcers.

Summary and Conclusions

The relative incidence of duodenal and gastric ulcers in hospital patients varies throughout Britain from 1 to 1 in London to 8 to 1 in Scotland.

Evidence is brought forward to suggest that the figures for London do not give a correct picture of the relative incidence of duodenal ulceration and gastric ulceration in that city.

The sex incidence of peptic ulceration is remarkably constant throughout the world, being approximately 3 males to 1 female.

The incidence of peptic ulceration in the Forces is what would be expected from the civilian pre-war figures.

The aetiology of duodenal and gastric ulcers varies in age incidence, familial tendency, and precipitating cause of onset.

It is suggested that psycho-physiological factors play the most important part in the production of duodenal ulcers, and that local trauma to the gastric mucosa plays the biggest part in the production of gastric ulcers.

I wish to express my indebtedness to Prof. L. S. P. Davidson for much help and encouragement in the preparation of this paper.

Detailed description and statistics have been omitted from the 1940 report of the work of the social service department, Samaritan Fund, of St. Thomas's Hospital. What speaks most eloquently is the description of the days after the first bombs had fallen on the hospital and surrounding district, an extract of which is given here to show how difficult and all the more necessary was the work of the Samaritan Fund during that time: "To Lambeth itself, the mere fact that the hospital during these dark days was continuing to treat patients had a steady effect only realized in full by those who were working there day in and day out throughout the period. Everywhere the normal and the abnormal were in strange juxtaposition. . . . Suffering was widespread. Many of the patients from one hour to another were rendered homeless. In many cases everything they treasured was lost. More than ever was it necessary for the almoners to do everything in their power to lessen and relieve the suffering in every way possible. . . . Very often the needs were small, even trivial, yet the fact that they were met promptly and adequately had a significance to the patient greatly in excess of the specific service given, for it meant that with a world in flux they could still feel that his hand is regarded them as individual human beings. Above suffering and anxieties were of consequence, whose removal is itself a something worth struggling for."

MEDICAL SUPERVISION OF INDUSTRIAL WORKERS

DICAL SUPERVISION OF INDUSTRIAL WORKERS

REPORT OF B.M.A. SPECIAL COMMITTEE

An important contribution to the war and post-war industrial situation is made by the report, just published, of a special Committee set up by the Council of the British Medical Association last year. The instruction to the committee was to make recommendations for the better co-ordination of industrial medical practice with the existing medical system, particularly with general practice and the public health and hospital services.

The personnel of the committee included eleven medical members; also a prominent Lancashire industrialist, a trade union leader, and the director of the Industrial Welfare Society. Observers attended from the Factory Department of the Ministry of Labour and from the Ministry of Supply. The committee confined its attention to the places of work covered by the Factory Acts; collieries were not included in its scope.

The report, presented by deputation to the Minister of Labour and National Service, outlines the place of medicine in industry and defines the duties of an industrial medical officer and the staffing of his department. The relations of the industrial with the outside medical services are mentioned, and there is a brief reference to rehabilitation, but the views of the Association on this last subject were fully set out in the report of the Committee on Fractures in 1935 and in the evidence submitted a year ago to the Royal Commission on Workmen's Compensation. Medical education for industry and industrial health research are the subject of some recommendations, and the final chapter is on the future of industrial medical practice. There are two appendices: one reproduces the ethical rules for the guidance of industrial medical officers in dealing with outside medical services, as approved by the Representative Body in 1937; and the other is a memorandum by the Association of Industrial Medical Officers on a syllabus for courses of instruction.

Place of Medicine in Industry

The starting-point taken by the committee is the view expressed by the Council of the B.M.A. that on both humanitarian and economic grounds the time is ripe for an extension of industrial medical service, and that more emphasis should be laid on the preventive aspects of industrial medicine, that there should be closer association between the medical profession and industry, and that the part played by industrial factors in the causation of disease should be more fully appreciated by both medical practitioners and employers.

Industry loses through the ill-health of workers 31½ million weeks' work in a year, and while it is not suggested that conditions in industry are the primary source of this loss, the environmental conditions during the working day must account for a large share. The loss resulting from accidents is estimated in terms of money at over 30 million pounds a year. But much of the time which might be lost as a result of them is saved if there are adequate arrangements for medical supervision. One firm reports complete disappearance of its special hazard—lead poisoning—as a result of medical care. In contrast with the average loss through illness of 10 days a year for men and 12½ for women (the figures are pre-war), firms employing from 700 to 6,000 workers have reduced this sickness absence, as a result of rendering medical service available, to from 3.75 to 5.25 days for men and from 4.5 to 7.9 days for women.

Medical supervision is not merely nursing, welfare, first aid, and accident prevention, or even the retention of a local practitioner on call in emergency. It implies continuous supervision of the health of the individual worker in his industrial environment, the prevention so far as possible of physical and

mental illness, a service for the initial treatment of injury, and efficient medical liaison between the factory and external medical services.

This does not necessarily mean an elaborate medical organization, beyond the capacity of small firms. Indeed, it is in the small firms that the future development of industrial medical practice must be expected, for they represent in total the larger proportion of the industrial population. More than half the number of factories in this country are small ones, employing fewer than 250 people.

Duties of an Industrial Medical Officer

A medical practitioner accepting a post in industry, whether part- or whole-time, must have some knowledge of industrial organization and factory methods, and must make himself familiar with the processes in his own factory. His duties can be set down under the following heads:

1. Medical supervision of employees during working hours.
2. Supervision of general working conditions.
3. Organization and supervision of accident service, including rehabilitation.
4. Study of specific occupational hazards and preventive measures for their control.
5. A.R.P. services.

Medical examination of new employees under 16 and of workers about to be employed in certain special processes is compulsory, but in the committee's opinion medical examination of other new entrants would be valuable in making possible the proper placing of workers. Workers returning after prolonged sick absence should be seen by the industrial medical officer. Here the general practitioner's knowledge of the medical history of the individual and the home conditions should be of value.

It is considered that the industrial medical officer should devote some of his time to advising individual workers. He should also encourage the management to undertake health education. Careful records should be kept, consisting of: (1) an ambulance room or casualty department book, (2) records (confidential) of medical examinations and individual case histories, and (3) statistical records of sickness absence.

As for accident service and rehabilitation, the medical officer must be responsible for securing that first-aid personnel are properly trained. Where there is a central casualty department he himself should train the staff, who would be responsible to him alone. Unfortunately the country does not as yet possess a comprehensive rehabilitation service, but the industrial medical officer will find that he can do a great deal to assist in the early return to suitable work of men who have been seriously injured. This again will call for close liaison with hospital officers and general practitioners.

Women in industry show a consistently higher sickness-absence rate than men, and this is not wholly explained by gynaecological conditions. A good deal of it must be attributed to the physical fatigue and consequent lowered resistance caused by the effort of running the home in addition to the work at the factory. The supervision of the health of the woman worker requires much assistance from trained welfare staff, but the industrial medical officer also has an important part to play. The employment of women during the later stages of pregnancy and the post-natal period will depend upon the circumstances of the woman and her work. Withdrawal from employment four weeks before confinement is usually sufficient, but in many cases it will be desirable for her to remain away from work for more than four weeks afterwards.

The practitioner entering industry should know something of toxicology and industrial hygiene. If he enters an industry in which a special hazard is attached this will have his attention. Inspection or medical examination of workers employed on dangerous processes will be carried out at frequent intervals. The medical officer will be in close contact with technicians, scientists, managers, and welfare supervisors, and much of the success of his efforts will depend upon his ability to work harmoniously with them, as well as to establish good relations with local general practitioners, hospital staffs, and public health

and Government officials. In the treatment of an individual patient there should be a continuous interchange of information between the various practitioners interested in the case.

Medical Officer's Appointment and Remuneration

The medical practitioner appointed to an industrial post should have wide sympathies and interests, good experience in general practice, some special knowledge of the treatment of injuries, an interest in occupational hazards, and an acquaintance with social conditions prevailing in industrial communities. He will be directly responsible for all health services in the factory to the managing director, but he should be given the greatest possible freedom in carrying out his duties. A large factory or factory with special hazards will find a whole-time appointment the most efficient and economical. Small firms may find it sufficient to appoint a part-time officer to attend at agreed intervals and on emergency. A number of such firms might combine in appointing a whole-time officer whose services would be apportioned among them.

For a medical officer in charge of medical work in a factory the minimum starting salary should be £800 a year; for an assistant medical officer, £600-£650. Payment in part-time appointments should be at a sessional fee of 1½ guineas for a session of not more than two hours, or payment may be by annual salary based on sessional rates. The scale just given relates to wartime conditions only. A whole-time officer should be given opportunities for postgraduate work and for clinical experience, possibly by acting as clinical assistant at the local hospital.

The direct appointment of the medical officer by the employer, who often has not the knowledge correctly to assess medical qualifications and suitability, is not altogether satisfactory unless he is suitably advised, and the committee suggests a central advisory body external to the factory, perhaps under the aegis of a Government Department, to guide employers in making a suitable choice. A successful precedent is quoted from Eire, where there is a Public Health Commission which receives all applications for public health appointments and submits its choice to the local authorities concerned. It is considered advantageous if the medical officer is enabled to transfer from one post to another without losing seniority; thus he would gather experience in different kinds and sizes of factories, much as a public health medical officer obtains experience in different types of local government appointments.

On the subject of nursing staff, it is considered that a fully trained State-registered nurse should be appointed in factories with over 500 employees in which whole-time supervision of the ambulance room is required; but there is also a place, especially in smaller factories, for the assistant nurse and the whole-time ambulance man.

Relations with Outside Medical Services

Only such treatment as is necessary during working hours should be undertaken at the factory, except in the case of certain industrial diseases which the industrial medical officer is specially qualified to treat. Any further treatment should be undertaken by the patient's own doctor or by the hospital to which he is referred. Factory patients presenting themselves to a general practitioner fall into three main categories:

1. Patients suffering from minor injuries, who can be treated entirely by the practitioner or referred to a hospital, and patients suffering from major injuries who are already under hospital treatment and attend for certification only.
2. Patients suffering from specific industrial diseases who for the most part are already under specialist hospital treatment, and are also seen for certification only.
3. Patients with common illnesses in the origin or development of which the conditions at the place of work may have played a part.

The problem is to increase the efficiency of the service which the patient's own doctor can give in the prevention and treatment of illness and accident arising from, or aggravated by, industrial environment. To this end much more emphasis needs to be placed in medical education on the relation of industry to health and disease. The committee makes the suggestion that

to the usual three histories noted in case-taking—namely, "past," "family," and "present conditions"—a fourth, "industrial," should be added. Another way of helping to solve the problem is again by interchange of information, the patient's doctor being kept informed of the progress of the illness which is being treated at the hospital or rehabilitation centre.

The need for a good working relationship between the general practitioner and the industrial medical officer is repeatedly stressed in the report. Such contact as at present exists is far too limited. It is suggested that the Divisions of the Association should consider what steps can be taken in their respective areas to promote means whereby the general practitioner can be brought into closer contact with the management of factories or with their medical officers. Visits of the medical profession to factories might be arranged.

"The object should be to arrange for the general practitioner facilities for making himself acquainted with the work of his patients or of any one patient so that this knowledge may help him to decide how far a patient's health is affected by his work and to advise and prescribe accordingly. On the other side, the industrial medical officer, where there is one, and the management of the factory would have the advantage of knowing the views of the patient's own doctor and of co-operating with him to the benefit of the patient and of the factory work. It is emphasized that the committee in making this suggestion has no desire to interfere with the Factory Medical Inspectorate or with the arrangements made by the management within the factory. Its only aim is to free the general practitioner from his present handicap of having to treat the patient without a full knowledge of the latter's working life and environment. Much help could be rendered by the employer if, when a practitioner feels that he needs for the efficient treatment of a particular patient some knowledge of the patient's working conditions, facilities could be given him to obtain that knowledge."

Hospitals, again, should make early notification to the doctor of a patient admitted directly for major injury, and the hospital staff should collaborate with the industrial medical officer and keep him informed of the patient's progress. The establishment of the Birmingham Accident Hospital and Rehabilitation Centre (the old Queen's) is mentioned. Any extension of hospital facilities for treatment of industrial accidents is to be welcomed, although the development of such special hospitals must be slow until there is a more adequate supply of (it is the committee's word, not ours) "traumatologists."

Medical Education and Research for Industry

Industrial medical practice is a comparatively new field, and the medical curriculum at present does not accurately equip the student with the knowledge that is necessary to treat industrial illness and injury and to recognize those factors in ordinary illness which are due to the industrial environment. The committee is of opinion that more university posts relating to industrial medical practice should be created. In each of the main clinical subjects of the curriculum the student's attention should be drawn to the industrial aspect, and he should be taught to understand the effects of occupation on health. The student who subsequently becomes a general practitioner in an industrial area will then possess a groundwork on which to base the treatment of his factory patients.

Postgraduate instruction for such general practitioners might well take the form of the organization of short courses, especially at the week-end, also addresses on industrial medical subjects at scientific meetings of the Divisions, more articles on industrial medical practice in the medical journals, and the organization of collective research by general practitioners on the relation of industry and disease.

As for research, at present no organization in this country equipped with the necessary staff and finance is available to conduct industrial medical research with skill and efficiency meaning by "research" the study by trained medical men with technical assistants and equipment, of the health of workers in relation to their employment. The Industrial Health Research Board is not able to spend money without the sanction of the Medical Research Council (of which it is an affiliated department), and, moreover, during the war, when a great

extension of its work might have been expected, its secretary is required to devote part of his time to acting as Chief Medical Officer to the Ministry of Supply. To the Factory Medical Inspectorate, even if they make use for research purposes of the material acquired in the course of their duties, research is only incidental to their main work. Some medical departments of individual firms do research work, but on the whole such research is sporadic and uncoordinated.

Scheme for Scientific Inquiry

The committee recommends that machinery, preferably on a national scale, should be devised to place industrial health research on an adequate and efficient basis. A partial scheme might immediately be set up to cover certain important industries, such as munitions, mining, and shipbuilding, or certain highly industrialized parts of the country, such as Birmingham, Manchester, or Glasgow. The work of the staff of these national or regional organizations would be: (1) to undertake research into industrial problems affecting health; (2) to collect and analyse sickness records; (3) to test in practice the theories formulated from such analysis; (4) to disseminate the knowledge wherever it can be applied of any definitely established fact that bears upon the health of the workers. The organizations should be set up in close association with existing universities. The staff should comprise both medical practitioners trained in research methods and technical assistants. Minimum equipment should include beds in a hospital, pathological and chemical laboratories, animal houses, and a library.

The keeping of records of all sickness absence should be compulsory, for such records must be the basis of industrial health research. "The type of information that might be made available is already provided with regard to occupational mortality in the Registrar-General's Decennial Supplements, where a mass of facts indicates work that might be done before the worker appears on the records because he is dead." Metal-grinders, for example, show a significant excess of deaths from certain causes; textile workers from certain others. As illustrations of the value of records, the observation of Alfred Greenwood in 1891 of the relation between cataract and glass-bottle finishing, gathered from a study of the superannuation lists of the Yorkshire United Trade Protection Society, and the discovery by S. R. Wilson in 1906 of mule-spinners' cancer from the records of the Manchester Royal Infirmary, are mentioned. A number of wide-scale problems, such as nutrition, fatigue, hygiene, and the prevention of respiratory disease, call for vigorous scientific investigations if the ill effects of wartime privations are to be avoided.

Future of Industrial Medical Practice

The report of the committee, which opened with a slight historical review, mentioning the first example recorded of a factory medical service (in Scotland almost exactly one hundred years ago), closes with a chapter discussing the possibilities of future development. In a well-planned health service the health problems of the industrial worker should receive more recognition than is at present given to them. Under existing conditions this service is more or less detached from the other medical services, due mainly to unplanned development. There is also a cleavage of responsibility in the matter of environmental health services. Outside the factory the public health authority controls, through its medical officer of health, water supplies, sewage systems, provision for infectious diseases, housing, and sale of food, but inside the factory very little control over hygiene is exercised in the name of medicine. Certain matters are controlled by the medical officer of health, many more by the Factory Inspection Department of the Ministry of Labour, but only a small proportion of factory inspectors—one for every half-million workers—are medical practitioners.

It will be necessary to decide whether there should be a single industrial medical service for the whole country, with a uniform method of appointment and remuneration, whether such service should be administered under the existing medical system directly under a Government Department or as a local authority function, or, if it is to form part of a State Medical Service, how it should be administered both centrally and locally. Whatever the ultimate form of the service, the committee, for a reason already touched upon in this summary, recommends

that there should be a uniform and generally acceptable procedure for the appointment of industrial medical officers. A single advisory body or an appointing body external to the factory should guide employers in the making of good appointments in a way acceptable to employers, workers, and medical practitioners alike.

The committee absolves itself from making any recommendations on the question of a full State Medical Service, the retention of the present system in its general framework, or intermediate forms of service. The Medical Planning Commission is at work on these problems, and its investigations will include the future of industrial medical practice. Whatever the ultimate form may be, the committee emphasizes its view that adequate provision should be made for the efficient co-ordination of factory health services with all other branches of health service, the association of the family doctor with the factory life of his patients, improved training and regular postgraduate courses for industrial medical officers, and systematic medical research in industry.

The report is published as a "grey book" by the British Medical Association (price 6d.).

CHEMISTRY AND PHARMACY

ADDRESS BY DR. HAROLD KING

The Hanbury medal of the Pharmaceutical Society of Great Britain was presented on November 13 to Dr. HAROLD KING of the National Institute for Medical Research. The President of the Society (Mr. WALTER DEACON), in making the presentation, described Daniel Hanbury, who was made F.R.S. in 1867, as one of the greatest pharmacists of all time.

Dr. King then gave an address on the relations of chemistry and pharmacy. The two subjects, he said, had been interdependent throughout the ages. As experimental sciences they were only between one hundred and two hundred years old, but as arts they had been practised from time immemorial. Their workshop traditions had been handed down from prehistoric ages, and it was not until the middle of the eighteenth century that chemistry began to blossom out of pharmacy and became a separate science. In a brief sketch of the early history of pharmacy Dr. King mentioned that the Babylonians and Assyrians knew of 250 drugs of vegetable origin, many of which served as the basis of the *Materia Medica* of the Greek physician Dioscorides of the first century of the Christian era.

The isolation of alkaloids, in very many cases by pharmacists, was the first important pharmaceutical development of the nineteenth century. In the current *British Pharmacopoeia* and its Addenda there were included twenty-one pure alkaloidal substances and their salts, and, of these, sixteen were first isolated by pharmacists. This early work on alkaloids was a great contribution made by pharmacy to chemistry. All those familiar with the changes in succeeding editions of the *British Pharmacopoeia* in recent years must have been struck by the decrease in the number of plants and the great increase in synthetic drugs included in it. It was instructive to examine how some of these substances originated. Many of the chemical substances were known for years before their therapeutic action was suspected. A number of them were laboratory curiosities of the chemist. It was not until forty-six years after its discovery that aspirin was introduced into therapeutics. Sulphänilamide was first prepared in 1908 in a search for components of dyes, but not until 1935, arising out of the German work on red prontosil, were its therapeutic properties discovered. Carbon tetrachloride was first prepared in 1840, but not until 1921 was its action on the hookworm recognized. Chloral hydrate was discovered in 1832 by Liebig, but only in 1869 were its hypnotic properties unmasked.

Speaking of the active principles which have been isolated from plant or animal tissues, including the majority of the alkaloids, hormones, and vitamins, Dr. King said that in the isolation of these principles or quintessences was to be seen the materialization of the dreams of Paracelsus, the first great pharmaceutical chemist. Substances which had risen mainly

as a result of organized research, with the pharmaceutical chemist and the pharmacologist in co-operation, including hypnotics, analgesics, anaesthetics, antiseptics, had been discovered, many of them in Germany, either in the universities or institutes or in the laboratories of large pharmaceutical organizations; and here the interval between the preparation of the substance and the discovery of its therapeutic properties had been quite short. Long-term organized research in pursuit of new drugs was the duty of large commercial organizations and subsidized undertakings, while the *laissez-faire* method of research should be the preserve of the university worker. What was needed in this country was more of the organized research into the chemistry of synthetic drugs and more pharmacological examination of the products of the chemical laboratory.

Finally, Dr. King mentioned some work which he had carried out on the alkaloids of curare. He said that he had been able to examine a specimen of curare which was deposited with the Pharmaceutical Society a hundred years ago, and this had enabled him to prepare in a crystalline state the active principle of one of the arrow poisons used by the South American natives. He had also been able to examine eleven species of *Strychnos*, and of these five had a curare action.

Sir HENRY DALE, in a few remarks after the address, endorsed what the lecturer had said about the enormous wealth of subjects offered by pharmacy to the chemist and through the chemist to the pharmacologist; just as, on the other hand, physiology and pharmacology in their turn were beginning to offer subjects to the chemist and through the chemist to the pharmacist.

Reports of Societies

PLACENTAL INFARCTS

At the last meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland, held in Dublin, with the President of the Academy (Mr. SETON PRINGLE) in the chair, Dr. N. FALKNER read his presidential address on the subject of placental infarcts.

Dr. Falkner alluded to the customary teaching with regard to these lesions and to the fact that most teachers in obstetrics did not attach much significance to their association with the toxæmias of pregnancy. He next described the work that Young had published in 1914. The main points in this work were the accurate description of the red infarct and its association with eclampsia. Prof. Young had evolved an attractive hypothesis and had made a most valuable contribution which included many interesting and stimulating statements with regard to placental anatomy and physiology. Recently workers in America had revived the views put forward by Young. Among these were Bartholomew and his co-workers. Careful examination of placentas from all toxæmic cases had resulted in the recognition of certain types of placental infarct in association with different clinical manifestations. Among the conclusions reached by these workers were: (1) Placental infarcts of the more acute types were definitely associated with the toxæmias of pregnancy. (2) It was possible to predict the type of infarct to be found in the placenta from a knowledge of the history. (3) With the experience of examining placentas as "unknowns," it had been found possible to establish criteria for an exact classification of placental infarcts and their relation to toxæmia. With regard to the significance of hypocholesteræmia and hypothyroidism as predisposing to infarcts in the placenta, the opinions of both Young and Bartholomew coincided in that they believed that the acute placental infarct had an aetiological significance. They differed in their interpretation of the causal factors producing these lesions.

Dr. Falkner showed sections from twenty cases of toxæmia of pregnancy and demonstrated the constant occurrence of acute infarcts in pre-eclampsia and eclampsia, and said that the older or more chronic infarcts were associated with nephritic toxæmias.

General Discussion

Dr. GIBBON FITZGIBBON said that he himself had made no investigations on this subject. He had found a few infarcts and had more or less discounted them as being causal elements in the toxæmias of pregnancy. Dr. BLUNT SETON said that the display of placentas that evening was extraordinarily interesting, but, alas! it shed little new light on the problem of the toxæmias. However, the work was valuable inasmuch as it might prove to be a link in the elucidation of the problem. It would be of great value if a series of placentas from normal cases were compared with a series of placentas from toxæmia cases. The relation of infarcts, and a good or bad decidual circulation, to toxæmias was still a puzzle. The general belief was that when infarcts were present with good decidual circulation the toxæmia was more severe.

The MASTER OF THE NATIONAL MATERNITY HOSPITAL referred to the very great delicacy of the vessels in the placenta, and said that the rate of growth of these vessels was enormous. When growth of this kind occurred something was bound to go wrong, and this would explain in some degree the development of infarcts. The most interesting question in his opinion was whether the toxæmia was due to the infarct or the infarct due to the toxæmia; he himself thought that the infarct was due to the toxæmia. Prof. A. H. DAVIDSON thought the chief question was, Did infarction come from the maternal circulation or from the foetal circulation? In his view it came from the latter.

Dr. R. M. CORBET had been greatly impressed with the researches of Bartholomew and his co-workers. While Dr. Falkner did not suggest that these infarcts were aetiological significant, Bartholomew was strongly of the opinion that they were the cause of the toxæmia. If this were so, it raised certain speculations. To have the foetal vessels primarily affected would postulate a hypercholesteræmia in the foetal circulation; also, the question might be raised why the foetus was not always affected to the same degree as the mother. Dr. Falkner had suggested that, when the infarction was acute, the whole cotyledon was involved. If this were so, the toxins liberated might not be absorbed by that cotyledon, but would be carried upwards in the maternal blood stream to the subchorionic pool, where there was little or no absorption, and thence into the general circulation, where they might be taken up by the maternal tissues before the blood returned to the placenta, thus leaving the foetus unaffected.

Dr. J. S. QUIN said that Dr. Falkner's paper must be looked upon as being only a very early progress report. He thought the question was, Were these lesions the cause or the effect of the toxæmia? Dr. W. R. F. COLLIS said that Dr. Falkner's paper was especially interesting from the point of view of foetal death and immature birth, which was the largest cause of foetal mortality. His experience was that in every case in which there was toxæmia in the mother there was toxæmia in the baby as well. Wherever the toxin was it certainly got into the foetal circulation. What were the cause and the mechanism of this actual thrombosis? Was it foetal or maternal? Had any work been done on the blood coagulation of babies born of eclamptic mothers?

Dr. FALKNER, in reply to the discussion, said that this work was still going on. The decidua had not been examined in any case; it was a most difficult thing to examine the decidua in the placental circulation. There were reasons to back up the view that disturbance of the maternal circulation would cause infarction. The greater proportion of patients who developed sugar in the urine during pregnancy developed albuminuria.

The Medical Director of Hospitals in Germany has recently stated that the special conditions brought about by war, and particularly in the areas liable to air raids, have made it necessary to have much more frequent blood transfusions than to man than used to be the case. In most cases blood transfusion is a life-saving measure for sick or wounded persons. As a result of an earlier appeal issued by the Party organization, people have offered themselves as blood donors, but now while the demand for blood donors has grown to large numbers more volunteers must be obtained.

Correspondence

Economy in Dressings

SIR,—Your leading article on the above subject (November 1, p. 619) is very opportune and draws attention to a matter of increasing importance at the present time.

It may be of interest to place on record that for the past seven years I have used perforated cellophane dressings in the case of all abdominal incisions in my department at the General Hospital, Birmingham, and am continuing the same at the Queen Elizabeth Hospital to-day. No gauze and no cotton-wool are used in "clean" cases. The cellophane adheres to the skin and is simply covered with a flannelette washable pad kept in place by tapes. For the first twenty-four hours a "many-tail" binder is also applied, mainly for the patient's comfort during the vomiting phase after anaesthesia.

Apart from economy in gauze and wool—both expensive items to-day—the nursing staff favour cellophane coverings to the wound because the method facilitates easy and rapid inspection of the area involved. The cellophane must be perforated before use to permit of evaporation from the skin.—I am, etc.,

Birmingham, Nov. 14.

BECKWITH WHITEHOUSE.

Infantile Scurvy

SIR,—We read with great gratification the announcement in the *Times* of November 12 that it is the Government's intention to distribute free fruit juice and cod-liver oil compounds at welfare centres.

In a recent investigation of the number of cases of infantile scurvy coming to hospital and seen in various clinics about London, there appears to be a slight but definite rise. The cases seen at the Hospital for Sick Children, Great Ormond Street, were as follows:

Year	No. of Cases of Scurvy	No. of New Patients Treated
1938	3	31,057
1939	3	24,307
1940	2	10,109
1941 (to Oct. 4)	5	6,474

Although this is a very small number (1941), it will be seen that there are relatively more cases when one takes into consideration the total number of new patients seen in 1941 as compared with the total numbers seen in the three preceding years. This suggests that more care must be paid by the welfare officers and others in instructing mothers in the prevention of scurvy. It should be pointed out that orange or tomato juice, or blackcurrant puree, is quite necessary, and that cod- or halibut-liver oil or some of the malt preparations are no substitute. Not less than four teaspoons of fruit juice appears to be necessary for children of 6 months and older. Ascorbic acid, from 30 to 50 mg. daily, should be substituted where natural vitamin C is not available, but should not be given for preference. After the age of 18 months to 2 years there appears to be plenty of vitamin C in the diet to cover the infant's requirements.

A great responsibility rests on infant welfare centres where proprietary malt preparations are dispensed and recommended, some of which are not even claimed by the makers to contain the minimum amount of vitamins. We have seen acute rickets develop on such preparations. Cod- or halibut-liver oil should, of course, be given throughout the winter months.—We are, etc.,

London, W.1, Nov. 14

Diagnosis of Helminth Cysts in the Brain

SIR,—Dr. L. J. Segal (November 15, p. 693) describes a case of suspected hydatid of the brain treated with sulphathiazole. The title of the paper describing this as "cysticercosis epilepsy" is surely misleading, for the author states quite definitely that "in view of these findings it was considered that the symptoms were due to the presence of a hydatid cyst of the brain."

But this diagnosis is apparently based solely on the discovery by x rays of a cyst about the size of a five-shilling piece in the left lung and "a suggestion of an infected left maxillary antrum." On the evidence available I think the diagnosis extremely doubtful. As the patient, while serving in the Navy in China, suffered from a "tropical disease," with loss of consciousness and with subsequent headaches and mental depression, I take advantage of Dr. Segal's request for comments to suggest that possibly this case is one of cerebral invasion with the eggs of *Schistosoma japonicum*, and that a microscopical examination of the faeces may even yet reveal their presence.—I am, etc.,

St Albans, Herts, Nov. 17.

R. T. LEIPER.

The Bombed Child and the Rorschach Test

SIR,—Dr. W. E. R. Mons (November 1, p. 625) suggests that the Rorschach test reveals the "bombed" child as a clinical entity, with special reference to K responses having a fire or explosive content given to the lower red in Card II. Since he adds that his findings must be regarded as tentative, pending records of a larger number of cases, it may be worth while, in corroboration, presenting the following small series, carried out with evacuee children in the County of Hunts, by kind permission of Dr. C. B. Moss-Blundell, county medical officer of health:

Age	Sex	Disorder	Response	Rorschach Determinant
15	F	Bombed:		
12	F	Hysterical fainting	Flames	K
12	F	Delinquent, unstable	Flames	K
12	M	Facial tic, enuresis	Nil	—
11	F	Unstable personality	A ray	K.C.
13	M	Compulsive pilfering	Sunset	K.C.
9	M	Enuresis, anxiety	Nil	—
12	M	Pilfering, aggressive	Horse's head	Ad
10	M	Pilfering, anxiety	Fire blaze	K
11	F	Anxiety state	The sun	K
8½	F	Facial tic, school failure	Guns going off	Km
		Unbombed:		
9	F	Psychopath c personality	Nil	—
10	M	Anxiety hysteria	Nil	—
10	M	Asthma, enuresis	Red fluid	Km.C.
10	M	Temper storms	Ink stain	C
12	M	Pre-psychotic, delinquent	Horse's head	Ad
9	M	Enuresis, anxiety	Church spire	Scene
12	M	Unstable personality	Animal	A
13	M	Anxiety	Bird's head	Ad
16	F	School failure	Part of butterfly	Ad

It will be seen that of these nineteen consecutive cases 70% of the bombed give fire or explosive K responses: the only K response in the unbombed group was given by a child who saw the results of severe bombing within two miles of his home, though his immediate neighbourhood did not suffer. As K is accepted by Rorschach authorities as a sign of disturbance in the deeper layers of the personality, these reactions seem significant, not necessarily of a "bomb-induced neurosis" (for some children in both groups showed symptoms of maladjustment before the war) but of serious endogenous anxiety aroused by traumatic experience.

There is another point of interest in this connexion. Klopfer describes the K response as indicative of mental "haziness or fog" created by anxiety; and also notes that such responses are often tinged with dysphoria. Such a condition would account for the commonly observed failure of bombed children to concentrate on school work, though they may struggle hard to do so.

As Dr. Mons points out, it would be unscientific to draw definite conclusions without examination of the whole Rorschach record in each instance and of a larger number of cases, but these preliminary results may perhaps serve to justify a fuller investigation into the effects of bombing upon children.—I am, etc.,

Huntingdon, Nov. 15.

A. T. ALCOCK,
Child Guidance Officer, Hunts.

Increase of Tuberculosis

SIR,—Dr. A. L. Jacobs (November 15, p. 703) notices my short letter (November 1, p. 632) in a somewhat formidable reply. In this he misquotes me by attributing to me the statement that the increase of tuberculosis at present evident "is to be explained entirely" by the discharge of a number of sana-

torium and hospital patients at the outbreak of war. I spoke of "the unwitting power of spreading the infection to those about them" possessed by the tuberculous, and, referring to the numerous theories now current on the subject, asked: "Is it necessary to postulate anything else?" I did not say or imply that the increase was to be explained entirely by the numbers of infective cases then added to those normally outside the sanatoria.

I am unable to accept Dr. Jacobs's statement that my contention as to the danger of infection is "one of the minor aspects of the problem." On the contrary, I consider it the keystone to the whole incidence of tuberculosis infection and disease. I take it, Sir, that Dr. Jacobs will not deny that clinically evident tuberculosis is due, in the first place, to infection. There may be, and are, secondary causes: poverty, unemployment, defective nutrition, close contacts, bad housing, want of resistance, and the various environmental disabilities; but infection is the one factor that underlies them all.

There is a great deal of poverty at present no doubt, but is there more or less than before the war? Is unemployment greater now than in pre-war England? Is it so much less as to be almost insignificant? Is nutrition really so very defective? There is not much clear evidence for or against in the incidence of proved "deficiency diseases." Bad housing and accommodation in shelters may lead to the spread of tuberculosis by bringing about more intimate contact between the tuberculous and the healthy, and there may well be a loss of resistance under the stress of war conditions, but, if so, this can only be operative by lowering the level at which infection leads on to disease. The National Association for the Prevention of Tuberculosis says, in a recent pronouncement, that "(a) in unselected samples of the normal apparently healthy adolescent population the incidence of definite pulmonary tuberculosis of the adult type is between 0.5% and 1%; (b) in unselected samples of contacts (using this word in its broadest sense) the incidence is between 3% and 6%." Opie, writing in 1935, said: "Since in persons exposed to tuberculosis after 15 years of age the frequency of infection, like that of early childhood under corresponding conditions, increases rapidly and far exceeds that of the general population, the adult type of pulmonary tuberculosis is evidently acquired by contact."

I fancy that Dr. Jacobs may have been a little too generous in allowing 15,000 as the number of tuberculous persons turned from sanatoria and hospitals in 1939, but it is safe to assume that they reckoned among their ranks a greater percentage of sputum-positive persons than those outside the institutes who keep up the normal entry by spreading the disease to others. It seems a fair guess, however, that those sent back to ordinary life were at least four times as many as the total number of persons constituting the "increase" since the beginning of the war. Nor is it true that those turned from sanatoria went back to a life the same as they had temporarily left. They emerged to find the nation at war. Many of them entered the Army and more still were evacuated to new homes and new surroundings to spread infection to comrades or to women and children in contact with them.

I will not quote my friend's epigram again, as it disturbs Dr. Jacobs, but I hope, Sir, that it will not be forgotten.—I am, etc.,

Cheam, Surrey, Nov. 20.

S. LYLE CUMMINS.

Hemiprostectomy for Unilateral Adenomatous Enlargement

SIR.—I was interested to read Mr. Sampson Handley's article on hemiprostectomy for unilateral adenomatous enlargement (November 15, p. 681). While admitting that hemiprostectomy should have a place in the operative treatment of benign prostatic enlargement, I do not agree with him when he states that in his opinion in about one case in five it may prove to be the operation of choice. In my opinion hemiprostectomy should be practised only in a really "bad risk" type of patient, much less often than Mr. Sampson Handley would seem to advocate. In my last 200 cases of simple enlargement of the prostate treated surgically I find I have performed hemiprostectomy four times.

Some of the disadvantages of the operation are: (1) Enlargement of the residual lobe may at a later date necessitate a

second operation. (2) The vesical outlet is not so large and therefore the outflow of urine is not so free as after complete prostatectomy, and as a consequence the suprapubic opening usually takes longer to heal. (3) Residual urine is more often present after hemiprostectomy than after the total operation. The disadvantages of the operation are very obvious, and must, therefore, be something present in the condition of the patient to make the complete operation very dangerous before hemiprostectomy is resorted to.

The following case on which I recently performed hemiprostectomy is typical of the class of patient for whom I should recommend this type of operation. A very stout man aged 66, about two months before consulting me, suffered from retention of urine; the retention was treated by catheterization and the insertion of a large de Pezzet tube. He suffered from bronchitis and cardiac disease, with oedema of the feet and legs. Sooner than continue with suprapubic drainage he decided to risk the second operation. He had an adenomatous enlargement of the right lobe, but no palpable enlargement of the left. I felt he would not stand the shock, etc., of a complete prostatectomy, and in consequence removed only the palpable enlargement on the right side. He made an uninterrupted recovery, and nineteen days after the operation the suprapubic opening was closed and he was passing urine without difficulty.—I am, etc.,

London, W.1, Nov. 20.

W. K. IRWIN.

National War Formulary

SIR.—Most of us will be pleased to have the new *National War Formulary*, but the way this is being introduced seems likely to cause unnecessary waste of drugs and expense for the chemists. Many of these have the old stock mixtures already made up and have laid in stocks of drugs for the winter. When the new *Formulary* is introduced on December 1 many of these stocks will lie idle or waste. It would seem wise to have a period during which doctors could order medicines according to the old *Formulary* or, if not in stock, according to the new, or, alternatively, for the chemist to be empowered to substitute equivalent mixtures according to the old *Formulary* in place of the new ones until his stocks are used up. The exact details may be difficult to arrange and may not satisfy the purist, but "needs must when the devil drives," and when it is necessary to economize drugs it seems wrong to allow existing stocks to be wasted.

I see that boric acid has finally come into official disfavour for external application, but before it is relegated to the limbo of the past it might be wise to remember what our fathers and grandfathers did with it in urinary infections. It was probably "the best drug ever" for the stinking urine of old people, now happily seldom seen or smelt. I have used most urinary antiseptics—hexamine, amphotropin, cytotropin, pyridium, neotropin, mandalates, and sulphonamides—and I still use a use for boric acid. It is one of the surest drugs for rendering the urine acid, and when there is any residual urine an ounce or two of boric lotion, preferably with a little eucalyptus and well diluted with water, will seldom cause any gastric irritation and will "keep the water sweet," as our forefathers used to say, better than anything else. When there is so much need to conserve the work of our chemical firms such a simple remedy should not be overlooked even though it is old-fashioned. It is especially useful where a patient is unwilling to adopt the special measures required for the successful use of the newer antiseptics, and, as should be in such cases, it is much cheaper.—I am, etc.,

Wimbor, Cheshire, Nov. 17.

W. N. FORD.

Hyaluronidase

SIR.—I am extremely interested in the association of hyaluronidase (November 15, p. 689). Your account of the work of Chain and Duthie, K. Meyer, and D. McLean indicates clearly that in the process of septicaemia a bacterial enzyme is formed capable of destroying at least part of the protective surrounding of normal cells—the hyaluronic acid. I think I am justified in claiming that this discovery goes some way to confirm the theory which I put forward last year (1) "Hypertonic Sodium Sulphate Treatment of Infected Wounds."

Lancet, February 3, 1940, p. 216) to explain the processes of septic inflammation and the effect of hypertonic saline applications—namely, that “the bacterial toxin . . . damages the cell wall; this becomes permeable to the osmotic pressure exerted between the slightly hypertonic cell protoplasm and the lymph outside, and immediately the cell begins to absorb water.” From this I deduced that all the signs of septic inflammation could be explained and the effect thereon of the application of hypertonic sodium sulphate.

The beneficial effects of such treatment are becoming generally recognized. Correspondence in the medical press and the inclusion in the new *National War Formulary* of a lotion containing 25% of sodium sulphate for the hypertonic treatment of war wounds and similar conditions are sufficient proof. But the theory which I put forward has also a certain practical value, particularly in relation to the treatment of burns. If I am correct, then the osmotic effect of the hypertonic solution is exerted not at the surface of the wound, where no semi-permeable membrane exists, but at the cell membranes in the tissues rendered semi-permeable by the enzymes of the bacteria. The diminution of cellular oedema resulting from this osmotic effect is then the cause of the reduction of the local excess of lymph among the tissues, not by removal towards the surface of the wound but by reabsorption along the lymph spaces and lymphatic capillaries, which had previously been choked by the cellular swelling. The importance of this will be at once recognized, because if this is true then it is correct to apply the hypertonic treatment even to large burns where the loss of lymph from the surface can be in itself serious, since such loss is diminished, not increased, by such applications; and this is, in fact, my own experience.—I am, etc.,

York, Nov. 16.

J. C. LYTH.

Myositis and Fibrositis

SIR,—“How long will both these terms [myositis and fibrositis] remain entirely devoid of pathological significance?” With all respect to the writer of your admirable leader on sciatic pain (November 15, p. 698), the answer seems to be: Until he is better acquainted with the literature on the subject.

Prof. Ralph Stockman, in his scholarly monograph *Rheumatism and Arthritis* (1920), says: “So far as I am aware it was William Balfour, an Edinburgh practitioner, who first described (1816) the occurrence of definite thickenings in chronic rheumatism, and thereby established the pathology of the condition.” During the next hundred years Balfour’s original observations were repeatedly confirmed, and the treatment which he advocated by “friction, percussion, and compression” is essentially the same as modern physiotherapy. In 1904 Gowers proposed the name “fibrositis” to describe the pathological condition responsible for lumbago; and in the same year Stockman published independently “a detailed account of the whole condition with a description of the histology and structure of the fibrous indurations, and showed that chronic rheumatism in all its forms depends on the presence of this chronically inflamed, pathological, new fibrous tissue.” It may well be that the application of modern histological technique will throw more light on the pathogenesis of chronic rheumatism, but it is certainly incorrect to imply that the subject has not yet been explored.—I am, etc.,

Bridge of Weir, Nov. 15.

STANLEY ALSTEAD.

Treatment of Hallux Valgus in Soldiers

SIR,—The various letters on this lesion will be read with interest by many of our profession, and as the lesion is all too common it is well that opinions should be expressed.

In my own experience excellent subjective, cosmetic, and functional results may be obtained in the large majority of these cases by any of the types of operation already mentioned. My failures, however, have led me to deal cautiously with certain cases. At one stage I adopted Keller’s operation unreservedly till I met with two disappointments. In one of these the patient was over 40 years of age and in the other under. The latter had an arthroplasty done, and yet in both cases a bridge of bone formed between the raw proximal end of the cut first phalanx and the excised exostosis on the metatarsal head. Both cases had been immobilized for three weeks. Just recently

in an over-40 case done two years ago I found extreme pain on walking localized to the base of the first toe. This is due to a large arthritic lip, which has grown laterally from the base of the first phalanx of the great toe. In this case the head of the first metatarsal bone only had been removed. I take it that the stimulus to this outgrowth is the undue strain placed on the lateral ligaments of the metatarso-phalangeal joint of the great toe, when that part was placed across in its more medial position. These ligaments were not tenotomized.

For some time now my personal view as to the operative treatment of hallux valgus has been to select the procedure that best suits each individual case, not forgetting that the frequent concomitant foot lesions must also receive appropriate attention. To complete certain cases and avoid bridges of bone, etc., may mean a two-stage operation. The final result must give no bunion, a painless and actively mobile great toe, and preserve the pillars of the transverse arch. Where I find it necessary to deal with the distal end of the first metatarsal bone in order to preserve the pillar, I incise the head so that the plantar end of the cut ends just where cartilage meets bone. This slanting cut allows for an easy 20 degrees of dorsiflexion as mentioned by Mr. Sayle Creer (*Journal*, November 15, p. 710).—I am, etc.,

Dundee, Nov. 14.

JOHN J. ROBB, M.B., F.R.C.S.Ed.

Testing Night Vision

SIR,—While Mr. N. Bishop Harman (November 1, p. 632) is correct in attributing my interest in dark adaptation to a vitamin motive, he will, I trust, allow that a requirement of the scientific approach to the problem is an investigation into methods of accurate measurement of dark adaptation, and my letter was concerned only with that aspect of the problem. In any case it is well established that the causes of faulty dark adaptation are many and varied.

During the investigation of many phenomena considerable modifications of view have resulted from refinement of instruments and techniques, and this has already held good for dark adaptation. Further knowledge of this phenomenon will depend upon our aiming at the highest accuracy, and it seems to us that a most useful development would be a sufficient standardization of methods and techniques (in the light of present knowledge) which will enable the results of different observers to be compared and correlated. In pursuit of this purpose there is considerable agreement that the following criteria of test conditions must be considered: previous light and dark adaptation; size and nature of test object, with control of illumination without alteration of spectral values; pupil diameter; fixation point; the data obtained to represent the whole or an appreciable part of the course of dark adaptation, and to be presented in a uniform manner.

In the light of the above we attempted to point out what seemed to be some of the limitations of Mr. Bishop Harman’s test. Mr. Bishop Harman says he could always reach his “normal” range in five minutes even when he came into the dark room from the bright sunshine. From this, and from the published figures of illumination used, it is clear that the whole test, in spite of the small variable range of illumination made possible by varying the distances, is carried out at a relatively high light intensity, far above the final rod threshold. This, of course, explains why improvement is not ascertainable upon retesting.

Regarding the accurate control of the test illumination, the “standard candle” has not been used as the standard of illumination since about 1900 for the reasons stated. We felt justified, therefore, in suggesting that the test should not be regarded as an accurate one.

The literature is now, of course, very extensive, but support of the above statements can be found in the following: “Dark Adaptation,” review of literature, D. Adams, *Medical Research Council*, 1929; “Review of Recent Literature,” Sloan, *Archives of Ophthalmology*, June, 1939, 21, 913; “Some Basic Principles of Dark Adaptation,” MacDonald, *Archives of Ophthalmology*, April, 1940, 23, 841; “Dark Adaptation,” Mandelbaum, *Archives of Ophthalmology*, August, 1941, 26, 203; “Rods, Cones, and the Chemical Basis of Vision,” Hacht, *Physiological Review*, April 17, 1937.—I am, etc.,

The Crookes Laboratories,

The Research Department, Nov. 18.

E. W. GODDING.

Staffing of Hospitals

SIR.—Critics of municipal hospitals have paid little attention to the gradual change in method of staffing all hospitals. The traditional staff of part-time consultants with resident house officers was first supplemented towards the close of last century by the appointment at teaching schools of full-time pathologists. Later, the clinical staffs were reinforced by the creation of registrars and resident surgical officers, and full-time anaesthetists followed.

In the years following the last war a number of London and Scottish schools altered the conditions of tenure of professorial chairs by restricting private practice and requiring more time to be devoted to hospital and teaching duties. About this time also a number of hospitals employed full-time radiologists. The most recent exhibition of this tendency is in regard to orthopaedic surgeons. "The results were often disastrous," says Mr. Watson Jones, "not because surgeons were lacking in skill, but because this skill was not available to the patient at the moment that it was most required." What is this but an argument in favour of the municipal method of staffing, and one, moreover, recently recognized in Birmingham by the establishment of an Accident Centre with a full-time director?

In view of this tendency enthusiasts for the voluntary system should pause before condemning the municipal, at any rate on the score of its method of staffing. It is also worthy of note that that favourite target—the medical superintendent—is not a recent municipal invention, but was begotten of the Scottish voluntary hospitals at a time when the consultants were "giants, but quarrelsome giants."—I am, etc.,

Burnley, Nov. 15

A. DUFF.

A Municipal Hospital

SIR.—The record of facts concerning the Redhill County Hospital, Edgware, as set out by its permanent staff (November 15, p. 711), looks quite Utopian on paper. With some experience of the scheme in practice there, I feel that the disadvantages should also be recorded.

1. That most pernicious of our national characteristics—the tendency to get into a complacent rut—is fostered by the security of tenure and financial security without private practice.

2. The two greatest stimulants to progress and initiative—namely, competition and the struggle for existence—are completely eliminated by this scheme.

The best-run, most progressive municipal hospital of my experience was presided over by a superintendent who may fairly be described as a benevolent tyrant. However, after many months under both systems, I am happy to be back in the voluntary hospital service.—I am, etc.,

Royal Infirmary, Preston, Nov. 16.

UNA M. WESTELL.

Diabetes and Chronic Nephritis

SIR.—Dr. Tadeusz Markowicz's letter on diabetes and chronic nephritis (November 8, p. 670) raises some interesting questions.

His letter does not display evidence of chronic nephritis in the case under consideration. Oedema can, I believe, be a feature of diabetes mellitus. No degenerative lesion of the kidney could be removed by an injection of mersalyl. The absence of albumin after the injection disproves the presence of a chronic kidney lesion. The functional disturbance to which albuminuria may be attributed is sufficient to account for a few epithelial cells and hyaline casts. Just what is the intimate mechanism which produces albuminuria is, so far as I know, unknown to medical science.

What was the action of the mersalyl and how did it produce its results? A possible explanation is that it altered the renal threshold. It was pointed out in these columns some years ago that a diabetic glucose-tolerance curve may be present without glycosuria. This must have been the situation five hours after the mersalyl, when the urine was sugar-free. The work done by the kidney in separating water and salts for excretion against the osmotic pull of a blood sugar of 226 mg. per 100 c.c.m. must be very great indeed. No theory of the physiology of the kidney can, so far as I can see, explain it.

None the less, the diuretic must be looked upon as responsible for the improvement in the general condition. The obvious suggestion is that the improvement of the water balance facili-

tated the function of the peripheral tissues, possibly increasing their capacity for using sugar.

The problem presented by the function of the kidney in diabetes calls to mind that the disease was first named on the polyuria. The pituitary, which is now being introduced into our picture of the dysfunction of diabetes mellitus, is associated with another form of polyuria in diabetes insipidus. But whereas substitution therapy with posterior lobe extract will abate polyuria in insipidus, removal of the gland increases it in the diabetic animal. If we assume, as is reasonable, that pituitary extract acts on the kidney in cases of diabetes mellitus, we are at a loss in any attempt to envisage the nature of that action by reason of our ignorance of the intimate nature of kidney function. It is, however, to be noticed that in cases of diabetes insipidus the kidney is able to separate even water from salts, an achievement similar to that required to explain the action of mersalyl in the present case.—I am, etc.,

Coventry, Nov. 18

K. E. BATES.

The Nutritive Value of Bread

SIR.—May I ask for space to reply to the criticism made by Dr. Margaret D. Wright (November 15, p. 689) of an experiment of mine in which comparison was made between the nutritive values of wholemeal and white flour to which extra vitamin B₁ was added (*Lancet*, October 26, 1940).

In my experiment two groups of litter-mate rats, 4 weeks old, received Diets 1 and 2 containing, respectively, 88% of white flour (73% extraction) and 82% of wholemeal (10% extraction). Both flours were obtained from the same wheat. In order to ensure optimum provision of protein and minerals both diets contained purified casein (6%) and salt mixture (2%); cotton-seed oil was also present (4%). All the rats received a daily dose of cod-liver oil to provide vitamins A and D, and those on Diet 1 also 10 µg. daily of pure vitamin B₁ to correct the deficiency in this vitamin. The rats on Diet 1 increased in weight (av. 12 g. weekly) at about one-half the rate of those on Diet 2 (av. 23 g. weekly); when after two weeks the diets were changed over, the relative growth rates changed correspondingly. The rats receiving Diet 2 ate more food but also made better use of it, the average weight of ingested dry food (2.3 g.) corresponding to a weight increase of 1 g., being about 30% less than was the case with Diet 1 (3.1 g.). From this result the conclusion was drawn that white flour, even when extra vitamin B₁ is given and the defects in protein and minerals also corrected, is still inferior in nutritive value to wholemeal. The residual defect was held to be a relative lack of the B vitamins, and this conclusion has since been confirmed by work carried out in this Division by Miss A. M. Copping, who has shown white flour to be inferior to wholemeal in its content of riboflavin, vitamin B₂, and "filtrate factors."

Dr. Wright's chief criticisms may be summarized and answered as follows:

1. Dr. Wright considers that the rats receiving the white flour diet increased in weight less rapidly because they ate less food and thus obtained less protein, the reason for the loss of appetite being not that this diet was less nutritious but that it was less palatable than the corresponding one made with wholemeal. Whatever the diet, increase of weight in young animals depends on the amount of food intake. Increased appetite, with corresponding increase of growth rate, is a common occurrence when, for example, an essential vitamin is added to a diet in which it has been hitherto lacking. This is a result of the enhanced nutritive value of the food, and occurs even when the vitamin is given as a minute dose of the pure crystalline salt and can have no effect on the palatability of the ration as a whole. The rats receiving the wholemeal diet in the experiment not only ate more of it but, as stated above, started to eat to better advantage than did those having the white flour diet.

2. Dr. Wright states that the rats receiving the white flour diet received less vitamin B₁ than those on the wholemeal diet. This may be true, but 10 µg. daily, which is the form of nutrient has been found more than adequate for normal growth rates of the age and weight employed.

3. Dr. Wright also considers that the rats receiving the white flour diet received less vitamin B₂ than those on the wholemeal diet, which contains the germ. Adequate vitamin B₂ was, however, supplied in both diets in the cotton-seed oil which was

In this laboratory rats have been reared for more than two generations on an artificial diet in which a small amount of cotton-seed oil was the only source of vitamin E.

4. The number of animals (nine in all) employed in my experiment is considered too small to enable satisfactory conclusions to be drawn. The results were, however, so clear-cut that I have no reason to doubt their significance. In my own experience, as much information may often be gained from nutritional trials on a few animals, individually observed and cared for, as from others involving large numbers.

One error in Dr. Wright's account of my work should be corrected—namely, the statement that my comparison was made between "a straight-run white flour (73% extraction)" and "wholemeal (82% extraction)." The "wholemeal" flour used by me contained, as the term signifies, 100% of the grain.—I am, etc.,

Division of Nutrition,
The Lister Institute, Nov. 23.

HARRIETTE CHICK.

Anglo-Soviet Medical Committee

SIR.—The Anglo-Soviet Medical Committee invites members of the medical and dental professions and students of these professions to give their support to the work of the Committee by becoming associate members. The aims of this body have already been published in medical and dental journals, but for those who did not see the original announcement they are as follows: (1) To form a liaison between the medical professions of both countries. (2) To exchange the latest clinical and scientific knowledge. (3) To facilitate visits of medical specialists between the two countries. (4) To give specialist advice on medical aid to the U.S.S.R.

It is proposed to make the minimum subscription for associate members 5s. per annum, the funds so raised to be used for the expenses of the Committee's work. A bulletin will be issued from time to time giving reports on the work accomplished by the Committee. A general meeting for members and associate members will be held early in the new year. Those who wish to become associate members should write to the hon. secretary, Anglo-Soviet Medical Committee, c/o the Royal Society of Medicine, 1, Wimpole Street, London, W.1. The Committee feels that there are many members of the medical and dental professions who would like to take this opportunity of contributing to the national effort and assisting our ally.—We are, etc.,

ALFRED WEBB-JOHNSON,
President.

H. HAROLD SCOTT,
Chairman of the Executive Committee.

PHILIP MANSON-BAHR.

JOHN A. RYLE,
Members of the Executive Committee.

Nov. 17.

Obituary

WILLIAM JAMES PENFOLD, M.B., C.M.Ed., B.Hy.
D.P.H.DURK.

The report of the death in Melbourne on October 27 of Dr. W. J. Penfold will be received with great regret by his former bacteriological confrères in this country, and by old colleagues who still retain a vivid memory of his personality and a very conscious appreciation of his scientific achievements during his eight years' sojourn (1903-16) at the Lister Institute, first as B.M.A. scholar and later as a member of the bacteriological staff.

Entering the research field as he did after some twelve years of medical practice it is remarkable that he so rapidly accommodated himself to the laboratory life and that he succeeded in producing in the short space of eight years work of such high quality and permanent value. All the time he was the thinker, tensely strung up until he could submit to experiment some idea that may have come to him overnight. At times, indeed, his fertile imagination presented him with ideas for experiment that in his own interest it seemed desirable to restrain him from exploiting, but throughout he proved him-

self a most acute observer, eminently judicious in drawing conclusions while determined to secure the last ounce of information from his data. In all he published some twenty-five papers during these eight years, the majority of which were concerned with the experimental study of variation and mutation in bacteria—a study which was then engaging the attention of many bacteriologists in this country and abroad. To this subject, particularly in connexion with the fermentative properties of *B. typhosum* and the coliform bacteria of the intestine, he made many significant and substantial contributions which cannot be detailed here, but I would stress that their significance was all the greater from the fact that with the co-operation of Harden and other biochemical colleagues he was able to throw light on the laws governing the variations studied and on the enzymic mechanisms possessed by the variant forms. On the subject of salvarsan fever, salt fever, and experimental fever following the introduction of bacterial pyrogens he collaborated in a valuable series of papers with the late Dr. E. C. Hort. At the King George Hospital in the early years of the last war he collaborated with the writer in an investigation of typhoid, paratyphoid, and dysentery cases from the Dardanelles, and with Dr. Major Greenwood he carried out an inquiry into the possibilities of preventive inoculation against meningococcal infection during the prevalence of cerebrospinal meningitis in Salisbury.

In 1916 Penfold resigned his post at the Lister to take over the organization and control of what are now the Commonwealth Serum Laboratories in Melbourne, with their many additional responsibilities in the manufacture of biological products of all kinds. The success of this establishment in the intervening years is in great measure due to Penfold's administrative and organizing powers during its formative phase and to the energy he threw into the formidable task set him on his arrival in Australia. Of necessity but none the less regrettably the new sphere of work broke the continuity of the researches to which he was so wholeheartedly devoted in England, but soon problems of a different kind attracted his attention. For a time he was greatly intrigued with and strongly advocated the practice of "refusion," by which is understood the returning to the horse of the deposited red cells from a bleeding, thus assisting the animal, or so it was believed, to sustain the loss of much greater quantities of blood within a short interval.

In 1927 Penfold resigned his directorship of the Commonwealth Serum Laboratories to take up the newly created post of Director of the Baker and Shaw Medical Research Institute attached to the Alfred Hospital, for the pathological work of which it also catered. Here, attracted by the varied pathological material available, Penfold was able to resume in great measure his research activities, and between 1927 and 1938, when he retired, he contributed to the *Medical Journal of Australia*, with the co-operation of various colleagues and pupils, including his son, H. B. Penfold, a steady flow of papers on a great variety of subjects, the mere titles of which give ample evidence of his curious, versatile, and inventive mind. In 1935 he gave the Bancroft Memorial Lecture on medical research in Australia, and in the same year took a prominent part in the work of the Annual Meeting of the British Medical Association in Melbourne. His retirement in 1938 from the Baker Institute was followed by many tributes to his work for Australia since his arrival there in 1916. In Melbourne scientific circles he will, I feel sure, be greatly missed, for he was a doughty controversialist and a ready speaker in debate on any platform, scientific or political. By those with whom he worked in London some thirty years ago he will be remembered as a most amiable and stimulating colleague. *Ave atque vale.*

J. C. G. L.

The following well-known medical men have died abroad: Dr. F. KAPKA, director of the psychiatric clinic at Prague; Dr. ALEXANDER WESTPHAL, professor of neurology and psychiatry at Bonn; Dr. HEINRICH KLEIN, professor of neurology and psychiatry at Leipzig, aged 66; Dr. MAX AARON GOLDSTEIN, founder and editor of the *Laryngoscope* and past president of the American Academy of Ophthalmology and Oto-laryngology, aged 71; Dr. MEYER BODANSKY, professor of pathological chemistry at the University of Texas School of Medicine and author of *Introduction to Biological Chemistry*, aged 45; and Dr. JOHN PRICE CROZER GIFFITH, emeritus professor of paediatrics in the University of Pennsylvania and author of a well-known textbook on diseases of infants and children.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Diploma in Medical Radiology and Electrology

The University of Cambridge has decided that the regulations for the Diploma in Medical Radiology and Electrology will be rescinded on October 31, 1942, and no examinations will be held and no diplomas granted after that date. The course which started in October, 1941, is therefore the last course that will be given for the diploma.

UNIVERSITY OF LONDON

LONDON HOSPITAL MEDICAL COLLEGE

Hutchinson Triennial Prize

The subject for the next Hutchinson Triennial Prize is "The Investigation and Treatment of Sciatic Pain," and dissertations must be delivered at the London Hospital by October 31, 1944. Full conditions may be obtained on application to the Dean of the London Hospital Medical College, Turner Street, Whitechapel, E.1.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council held on November 14 the following appointments were made:

Medical Tutors, Drs. H. P. Brody and J. Pemberton. *Surgical Tutors*, Messrs. A. W. Fawcett and H. Blacow Yates. *Obstetrical Tutor*, Dr. W. J. McCord. *Honorary Lecturer in Applied Anatomy*, Mr. J. T. Chesterman. *Research Assistant to the Department of Pathology and to the University Cancer Research Laboratories*, Dr. M. J. Pivawer. *Representatives on the Committee of Management of Sheffield Hospitals Council*, Profs. H. N. Green and E. J. Wayne.

UNIVERSITY OF WALES

WELSH NATIONAL SCHOOL OF MEDICINE

The following candidate has satisfied the examiners at the examination indicated:

M.B., B.Ch.—*Medicine*: A. A. Edwards.

The Services

HONORARY SURGEONS TO THE KING

Major-General G. Wilson, C.B.E., M.C., late R.A.M.C., and Colonel (temporary Brigadier) D. T. Richardson, M.C., late R.A.M.C., have been appointed Honorary Surgeons to the King in succession to Major-General A. D. Fraser, D.S.O., M.C., late R.A.M.C., retired, and Major-General F. Casement, D.S.O., late R.A.M.C., retired, respectively.

HOME GUARD AWARD

The M.B.E. has been awarded to Lieutenant George Dunlue Eccles, M.C., M.B., B.S., Home Guard (Dawlish), in recognition of conspicuous gallantry in carrying out hazardous work in a very brave manner.

CASUALTIES IN THE MEDICAL SERVICES

ROYAL NAVY

Surgeon Lieut. FREDERICK BAGOT, R.N.V.R., is posted as "Missing, Presumed Killed," in an Admiralty Casualty List published on November 19. He was educated at the University of Manchester, where he graduated M.B., Ch.B., in 1932. He had held the post of house-surgeon at Ancoats Hospital and at St. Mary's Maternity Hospital, Manchester, and specialist house-surgeon at Manchester Royal Infirmary. Before the war he was in practice at Chorlton-cum-Hardy. He entered the R.N.V.R. as probationary surgeon lieutenant in October, 1938, and was confirmed in that rank one year later. In the *Journal* of July 12 (p. 72) we announced that Surgeon Lieut. Bagot had been mentioned in dispatches "for good services in the last six months or more of war." He was a member of the British Medical Association.

Wounded or Injured

Probationary Temporary Surgeon Lieut. Thomas McGowan Watt, R.N.V.R.

ROYAL ARMY MEDICAL CORPS

Captain WILLIAM DAVID MOORE, who died on November 12 as the result of a road accident, was educated at the University of Edinburgh, where he graduated M.B., Ch.B., in 1927. He was in practice in Edinburgh until 1935, when he moved to Blackburn, and soon after the war broke out entered the

R.A.M.C. as lieutenant, being promoted to captain a year later. He was attached to the R.A.O.C. The funeral took place in Workshop on November 17.

ROYAL AIR FORCE

Flying Officer HAROLD SIDNEY MELLOWS, R.A.F.V.R., died on November, aged 31. He was the son of the late Alderman W. M. and Mrs. Mellows, and received his medical education at King's College Hospital, qualifying M.R.C.S., L.R.C.P., in 1935. He also took the Cambridge degrees of B.Chir. in 1935 and M.B. in 1937. After holding the post of house-surgeon at King's College Hospital he settled in practice at West Wickham, Kent. He entered the R.A.F.V.R. as flying officer in 1940.

Flying Officer ANTONY FLEMING BALDWIN, R.A.F., who is reported "missing but presumed to have lost his life" on active service in the Middle East, was the eldest son of Mrs. C. J. Baldwin and the late Captain C. F. Baldwin. He graduated M.B., B.S. of the University of London in 1940 and, after holding junior house posts at St. Bartholomew's Hospital, entered the R.A.F. as flying officer in the same year. He was a member of the British Medical Association.

Medical Notes in Parliament

Home Guard Medical Officers

Mr. GROVES asked on November 18 if the Secretary of State for War would raise the age of enlistment for Home Guard medical officers, since over-age doctors still in practice must necessarily be employed but could not benefit from classes of instruction, etc., unless they were actually enrolled in the Home Guard. Captain MARGESSON replied that cases of this kind were considered on their merits. In general the upper age limit was not strictly enforced in the case of medical practitioners wishing to enrol as medical officers in the Home Guard, provided that they were fit.

Mr. GROVES also asked whether it was the considered policy of his Department that some medical advisers of the Home Guard should be appointed from among the whole-time servants of local authorities; and, if so, whether he would give an assurance that such officers had sufficient time for the duties which would be imposed upon them. Captain MARGESSON said that to avoid undue interference with the medical organization of the locality it had been decided that no medical practitioner might be enrolled in the Home Guard unless previous permission had been given by the Local Medical War Committee, which was aware of the professional commitments of practitioners in its area. This should ensure that Home Guard appointments were not inconsistent with the fulfilment of a practitioner's existing obligations. Replying to another question, Captain MARGESSON said a course for Home Guard medical officers had been arranged for next month, and further courses would be held as found necessary. Instructions and information regarding such courses were issued through the normal military channels.

On the same day Mr. GROVES asked the Minister of Health whether he was aware that in various parts of the country whole-time medical officers of health, already overworked by the addition of A.R.P. duties to those which they had previously undertaken, were now assuming the duties of Home Guard medical officers, involving the training of men and a great deal of administrative work, and whether arrangements were being made for recognition of such services. Mr. FOSTER-BELL said: I understand that some medical officers of health have found it possible to undertake the duties of Home Guard medical officers in addition to their official duties, the appointments being on an honorary basis as in the case of all other Home Guard medical officers. I am sure that their action in so doing is greatly appreciated by the Secretary of State for War. When approving the appointment of these medical officers the Local Medical War Committee no doubt paid due regard to their other commitments.

American Doctors in the F.M.S.

On November 19 Sir ELMER GASTON-LITTLE, M.P., Minister of Health to what services the medical practitioners coming from the United States of America to take up work in

this country were being allotted; to what body their original selection and ultimate distribution were entrusted; what remuneration was offered to them; and what remission of the rate of income-tax imposed on British subjects was accorded to them on the salaries paid to them in this country in respect of such service.

Mr. ERNEST BROWN replied: The doctors referred to are being allotted either to the E.M.S. or to the R.A.M.C. according to their own choice. The selection of the doctors, so far as their professional qualifications are concerned, is carried out in America through the National Research Council, the American Medical Association, and other professional bodies. Medical examinations and interviews are arranged in America on behalf of His Majesty's Government. Doctors who choose the E.M.S. are posted to hospitals by the Director-General E.M.S. The remuneration offered to them is the salary appropriate to the grade of medical officer in the E.M.S.—namely, £550 a year plus board and lodging or £100 a year in lieu thereof. I understand that this remuneration is subject to British income tax in the ordinary way, but the amount of the tax is repaid to the doctors by my Department, subject to the deduction of a sum equivalent to American income tax at current rates. The distribution and remuneration of those doctors who elect to serve in the R.A.M.C. are matters for the Secretary of State for War.

EPIDEMIOLOGICAL NOTES

Discussion of Table

A general rise in the incidence of infectious diseases, with the exception of paratyphoid and typhoid, occurred during the week in England and Wales. This increase contrasts sharply with the decline recorded in the preceding week. The increase in the notifications of diphtheria, 154 cases, was confined to the northern sections of the country; the largest increases were those of the north-western counties 54, and Wales 42. In London and the southern counties the incidence of diphtheria declined. The rise in the number of cases of scarlet fever, 162, was fairly general throughout the country, and so was the increased incidence of pneumonia, although this was greatest in the northern counties. The number of cases of measles was 123 in excess of the total for the preceding week. The increase was mainly contributed by the sharp outbreak in Kent, Easby R.D., where 94 cases were notified compared with 5 in the previous week.

In Scotland the number of notifications of diphtheria and scarlet fever declined, while the cases of whooping-cough and measles exceeded in number the total of the previous week.

Dysentery

No new outbreak of any size was reported during the week in England and Wales, the largest being that of Berkshire, Windsor R.D. 4. The rise in the notifications, 25 cases, was due to increased incidence in the local outbreaks reported in the preceding week. The chief of these were: London, Wandsworth 9; Surrey, Coulsdon and Purley U.D. 18; Staffordshire, Lichfield R.D. 17; Lancashire, Blackburn R.D. 17; and Whiston R.D. 5; Northumberland, Newcastle C.B. 5, and Gosforth U.D. 4. In Scotland the principal centres of infection were in the burghs of Greenock 10, Aberdeen 12, and Edinburgh 16.

Poliomyelitis

Thirty-three cases of poliomyelitis, an increase of 10, were notified during the week in England and Wales. The largest county totals returned were Kent 5 and Lancashire 4. Multiple cases occurred in the administrative areas of Berkshire, Wokingham R.D. 2; Kent, Crayford U.D. 3; Norfolk, St. Faith's and Aylsham R.D. 2; Wiltshire, Amesbury R.D. 2. One of the 2 cases reported in Scotland was recorded in Edinburgh: during the past four weeks 8 cases have been notified in this city.

Returns for the Week Ending November 15

The number of cases of infectious diseases notified during the week included scarlet fever 1,352, whooping-cough 2,066, diphtheria 1,043, measles 671, pneumonia 997, cerebrospinal fever 104, poliomyelitis 21, dysentery 204, paratyphoid 30, typhoid 9. Thirty-eight deaths were attributed to influenza.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended November 8.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (ad. Figures only). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Notification in certain administrative areas only.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

On December 1, 2, and 3 Dr. E. V. McCollum, Professor of Nutrition, School of Hygiene, Johns Hopkins University, Baltimore, U.S.A., will deliver, in Convocation Hall at the University of Toronto, Canada, the Harben Lectures for 1941 upon "Nutritional Science and Public Health." These lectures are delivered annually under the auspices of the Royal Institute of Public Health and Hygiene in accordance with the terms of the Harben Trust.

Sir Stewart Duke-Elder will deliver a lecture on "Ophthalmological Problems in War" at the Weston Hotel, Bath, on Thursday, December 4, at 5.30 p.m. All Service medical officers and civilian practitioners will be welcome.

A Chadwick Public Lecture on "Post-war Housing in the Light of Wartime Experience" will be given by Mrs. Blaise Gillie at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W.1, on Tuesday, December 9, at 2.30 p.m.

A joint meeting of the Society of Public Analysts and Other Analytical Chemists with the Food Group of the Society of Chemical Industry will be held at the Chemical Society's rooms, Burlington House, Piccadilly, W., on Wednesday, December 3. The meeting will be held in two sessions, beginning at 11.30 a.m. and 2.30 p.m. respectively, and the subject will be "The Fortification (Enrichment) of Human Foods by Addition of Specific Nutrients." The following papers will be read: at the morning session, "The Nutritional Bases for Fortification of Foods," by Mr. A. L. Bacharach, and "The Technological Aspect of Fortification," by Messrs. D. W. Kent-Jones and A. J. Amos; at the afternoon session, "The Machinery for the Enforcement of Standards for Fortified Foods," by Mr. H. E. Cox, D.Sc., and "Analysis of Fortified Foods," by Mr. H. E. Monk.

A joint meeting of the Sections of Laryngology and Otolaryngology of the Royal Society of Medicine will be held on Friday, December 5, at 10.30 a.m., when there will be a discussion on "The Effects of Flying on the Nose and Ear." Opening papers will be read by Wing Commander J. F. Simpson, Group Captain E. D. D. Dickson, and Squadron Leaders D. B. Fry, J. E. McGibbon, and R. H. Winfield.

The Ministry of Health has just issued a memorandum on Louse-borne Typhus Fever (Memo. 252/Med.). This briefly summarizes the principal facts about the disease and gives information which will aid local authorities in dealing with any occurrence that might arise.

Lieut.-Colonel R. Brooke, O.B.E., R.A.M.C. (Inner Temple); Major F. H. Blackburn, R.A.M.C., and Mr. E. A. Butterworth, F.R.C.S. (Middle Temple); and Dr. A. P. Ll. Cogswell (Gray's Inn) were called to the Bar on November 17.

Air Vice-Marshal Sir David Munro, Chief Medical Officer of the Ministry of Supply, will open the new medical department at the Longbridge Works of the Austin Motor Company, Ltd., on Wednesday, December 3, at 3 p.m.

The Ministry of Food, in co-operation with the Ministry of Health, has arranged for the free distribution from December 8 of fruit juices and cod-liver oil compound to all children born after January 1, 1940.

Dr. Zing-Yang Kuo, director of the Institute of Physiology and Psychology at Chungking, is on a visit to this country at the request of the Minister of Education for China and by invitation of the Universities' China Committee in London, his object being to promote closer and more effective cultural and educational co-operation between the two countries.

It has been decided not to award any Nobel Prize this year.

Mr. Ernest Brown, Minister of Health, stated recently that up to the end of September A.R.P. first-aid posts in the London region had dealt with 51,554 casualties.

Jewish doctors in Germany who have been authorized to practise again owing to the scarcity of "Aryan" doctors are not permitted to engage "Aryan" nurses to assist them, and Jewish nurses are not allowed to assist "Aryan" doctors.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* and unless the contrary be stated.

Authors desiring REPRINTS of their articles must communicate with the Secretary, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertising Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be addressed to the Secretary.

TELEPHONE NO.—B.M.A. and B.M.J.: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitology Westcent*, London. SECRETARY, *Mediscera Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumshugh Gardens, Edinburgh.

QUERIES AND ANSWERS

Treatment of Chilblains

Dr. C. M. STEVENSON (Cambridge) writes in reply to D. P. Binnington (November 15, p. 716): May I suggest that the most satisfactory treatment is the intramuscular injection of sodium cacodylate. Twelve minims of a 10% solution in water, repeated if necessary in two weeks' time, will usually give relief for several months. It is simple, and troublesome to neither doctor nor patient.

Congested Hands, Brittle Nails, and Dental Sepsis

Dr. E. U. MACWILLIAM (Bexley, Kent) writes: In this connection the following case may be of interest. A man aged 54 has suffered from congested hands (as described by "Status," October 14, p. 568) since childhood. About five years ago the finger-nails began to become thin and brittle, and since then most of the nails at one time or another became partially detached from the bed. As a rule the condition came on gradually, in some cases affecting almost the whole of the nail, and disappeared in a similar manner. Eight weeks ago, when the mouth was cleared of teeth, several of which were obviously infected, four nails of one hand and three of the other were affected as described. To-day all nails are practically normal. There is also a slight improvement in the congestive condition.

LETTERS, NOTES, ETC.

District Nurse for Home Guard Casualties

Major J. L. FORMAN BULL, medical officer, 5th Montagu Rifles Battalion, Home Guard, writes: In the *Journal of Nursing* (p. 680) you quote the Editor of the *Nursing Mirror* as suggesting that the local district nurses should be utilized to organize casualty collecting posts, especially in isolated country districts. As the Home Guard battalion area, thanks to the energy and foresight of the W.V.S., this scheme has been in existence for some time and has been amplified. The area covers about 200 square miles and is sparsely populated. In the larger centres of population there are first-aid points in charge either of the local district nurse or, where there is no district nurse, of a retired nurse. Each post has a voluntary staff of women who have had a course of training in home nursing and first aid, and is well equipped to deal with casualties even if they have to be retained in the post for four hours or more. In addition there are sub-points in more isolated areas in charge of women who have had a short course of nursing experience or have taken a course of home nursing and first aid. A supply of dressings, etc., is kept in their possession, and they can be used as temporary casualty collecting posts. The points have a notice displayed, "First Aid Point," and the sub-points one, "First Aid Dispensary." Altogether there are some sixteen first-aid points and six sub-points, and all of them are being organized as time goes on. Distress is not a factor in casualty collecting post within any section of the post in the battalion area where fighting may occur. As the district nurse may not always be available a second opinion is usually obtained preferably an ambulance is approached for transport and aid.

Paper Salvage

Dr. A. R. NEWMAN (Bristol) writes: The *Journal of Nursing* and *Cardiology* is great. There should be large quantities of it used with old newspapers and other waste paper to make a quickly available source of fuel for the boiler.

OBSERVATIONS ON SOME NORMAL AND INJURIOUS EFFECTS OF COLD UPON THE SKIN AND UNDERLYING TISSUES

I. REACTIONS TO COLD, AND INJURY OF NORMAL SKIN*

BY

SIR THOMAS LEWIS, M.D., F.R.C.P., F.R.S.

Physician to University College Hospital

The need to understand the reactions of the human skin and underlying tissues to cold increases with time. Men ascend to greater heights on mountain and in air; they go down to work deeper beneath the surface of the sea; and in these ascents and descents they become more exposed to the influence of cold. They work in the artificial coldness of storage chambers. And in wartime many are exposed to the cold of wet trenches or to the icy waters of the sea for long periods. Women, for their part, reduce to vanishing-point the clothing which long experience has taught us it is wise to wear on the limbs in wintry weather. It is my purpose in these lectures briefly to review work relevant to the injurious effects of cold, work that has occupied the attention of my co-workers and myself from time to time for a number of years.

Cooling and its Effects on Blood Flow to the Skin

If a person who is comfortably warm—that is to say, with skin temperature everywhere within a few degrees of blood heat—enters and sits at rest in a cold room the temperature of the skin begins to fall. In the absence of an obvious source of radiant heat, a room temperature of 16° C. (61° F.) will cause progressive cooling in most people; in many it will take place at 18° C. (64° F.); in some it will occur at 20° C. (68° F.). This progressive cooling is shown chiefly by certain parts of the body, where it will continue until the temperature approaches that of the surrounding air. Parts of the body so affected are those presenting a surface that is large in relation to their mass. The extremities of the limbs, and especially the digits, cool fastest and most. Of the face, the ears and nose cool most rapidly, for they, too, have relatively large surfaces; but they do not cool as fast or as far as the digits (Lewis, 1931). The rate and degree of cooling are usually displayed in the order: fingers (and toes), ears, and nose. These are the only parts of the body in which cooling is usually profound in the circumstances described, and fingers and toes are the only parts in which cooling often occurs down nearly to room temperature. Such cooling takes half an hour or more. The presence of clothing naturally influences the result, especially if the air of the room is in motion, for clothing holds a layer of warmer air on the skin's surface. Out of doors in a cold wind, if the subject is walking, the feet will be kept warm by the friction and by increased blood flow to the working muscles of the limb. The fingers and ears in such conditions will cool most, and the fingers more than the ears if the former are uncovered. There will be variations, according to the precise circumstances of exposure and

from subject to subject. Immersion in water brings the skin near to the temperature of its surroundings in a very few minutes, and much faster than exposure to cold air, though again more rapidly and more completely in parts that, like the digits, have large surfaces.

Effect on Blood Flow.—When the body surface is exposed to cold the vessels of the skin normally contract, blood flow is reduced, and heat loss from the skin is diminished. This vasoconstriction is a complex response; indeed, it comprises three separate reactions. First, there is a direct and persistent response of the superficial vessels to cold; they contract locally. Secondly, cold when applied to any part of the skin causes an immediate general vasoconstriction by reflex action through the central nervous system. This reflex, however, is only transient. It is succeeded and replaced by the third response. Cold venous blood returning from the cooled skin joins and lowers the temperature of the blood in the general circulation. This blood travels to, and acts upon, a central nervous mechanism, which is very sensitive to cold and responds by calling forth a general vasoconstriction, which is persistent. The second reaction is easily displayed; for if a limb is cooled while the circulation to it is cut off there is an immediate and transient general vasoconstriction; but the third reaction takes place only when the circulation to the cooled limb is restored (Pickering, 1932). In these vasoconstrictions, whether brought about locally or generally, all surface vessels—arteries, arterioles, capillaries, venules, and veins—participate.

All blood passing through the capillaries of the skin must come to the surface and enter the dense networks of the subpapillary venule plexuses, the blood in which gives colour to the skin. These plexuses act as efficient radiators when blood flows rapidly through them. There is, too, in certain parts of the skin an additional apparatus for heat dispersal—namely, the arteriolo-venous anastomoses, which, situated mainly at the very extremities of the limbs or digits, are able to convey a torrent of blood close to the surface. These additional radiators also respond to cold both directly, and indirectly through the nervous system, and so by closing form part of the mechanism of heat conservation (Grant, 1930; Grant and Bland, 1931; Grant and Pearson, 1938). Briefly, the skin is a most important organ in the regulation of body temperature; for, while it can rapidly dissipate heat when the body should be rid of it, it can conserve heat when the body should retain it.

The complex mechanism here briefly described constitutes a general defence of the body against cold; but, in thus acting, those parts which contain the radiators are

* The first of three Holme lectures delivered at University College Hospital. Lectures II and III will appear in our next two issues.

sacrificed. For a closing-down of the limb vessels, while safeguarding against excessive fall of body temperature, simultaneously ensures a fall of limb temperature. Moreover, the cooling of the limb, with its contained vessels, brings as it proceeds a greater closure of these same vessels in its train. Thus, locally, a vicious circle is established, which gradually carries the temperature of the limb closer and closer to that of its surroundings.

A fall of temperature to 10° C. (50° F.) or lower always benumbs the skin after a time, so that fine touch sense, and ultimately all touch and pain sense, is lost; it weakens the muscles of the limbs, and particularly those of the hand, by cooling them and their motor nerves; it no doubt interferes with the local proprioceptor mechanism and with fine control of movement, which depends on this. Thus the limb, and especially its extremity, in virtue of its sacrifice becomes a relatively inefficient member. But the sacrifice does not end here; there is abundant evidence, presently to be reviewed, that cooling beyond certain points injures the skin. The skin possesses its own local mechanism, which to a point meets this danger.

The Skin's Local Defence

If a finger is dipped into and held in a mixture of ice and water its surface temperature rapidly falls until it is not far above freezing-point; the deep parts of the skin cool almost as much, and the whole process occupies but a few minutes. When the finger is thus robbed of its natural heat it becomes the seat of pain, and this continues as long as the finger is maintained in its cold surroundings. But in five to twenty minutes the pain lessens; the finger feels comfortable, it no longer feels even cold, and observation shows that its temperature is rising. It becomes the seat of a local vasodilatation (Lewis, 1930). This vasodilatation is short-lived, but while it lasts it is intense enough to raise the temperature of the still-immersed finger 5° C. (9° F.) or even as much as 8° C. (14° F.); and it is sufficiently intense to bring the temperature of the cooled finger—if this is withdrawn from the water—well above that of the uncooled fingers of the same hand. This response of the cooled finger does not persist; for vasodilatation, with its warmth, is succeeded by a swing back towards a more usual vascular tone, and at once the temperature of the immersed finger begins to fall again and, cooling sufficiently, the whole process is repeated. Thus the temperature of the immersed finger rises and falls periodically; but as a result its mean temperature is very appreciably raised.

This vascular response of the skin happens not only when digits (fingers or toes) are immersed but when skin of the face, notably that of the ears, chin, and nose, is cooled excessively either by immersion in cold water or by exposure in cold air or wind (Lewis, 1930, 1931). It is a response which is far less in evidence in the skin of the rest of the body. It depends upon a local or axon reflex, for it does not occur in fingers the cutaneous nerves of which have degenerated; it is lost six to ten days after such nerves are cut—namely, at the time at which degeneration happens (Lewis, 1930; Lewis and Pickering, 1936). It returns when these nerves regenerate. The persistent coldness of fingers which have lost their nerve supply is in large part due to the absence of this reflex; and persistent coldness is thought to be responsible for much of the pathological change which is apt to occur in such fingers (Lewis, 1930; Lewis and Pickering, 1936).

The defensive reaction of the skin described is vigorous when cooling proceeds near to the freezing-point of water; but careful observation shows that it begins to be recognizable at temperatures as high as 15° C. (59° F.) or occa-

sionally even 18° C. (64° F.). Thus it happens at temperatures which skin of digits often experiences out of doors during winter months in this country; and the reaction has been shown actually to occur in such circumstances. It is very notable in the hands after snow has been much handled. The response undoubtedly constitutes an important defence against cold, though it will be understood that the defence is incomplete. It appears when cold begins to produce effects on the skin which independent evidence suggests may result from injury. The defensive response to excessive cooling which we are discussing is almost certainly an actual reaction to injury, and related in its degree to the extent of injury.

Evidence that Cold Injures Normal Skin

It is important fully to realize that cold affects the normal skin in two distinct ways. It may damage the skin by direct action or by causing it to freeze. These two effects have often been confused; both have often been described under the term "frost-bite." To avoid such confusion I shall limit that term strictly to effects which follow freezing of the skin, and shall defer consideration of this subject until later. Here I propose first to discuss experimental evidence that normal skin can be injured by reduction of its temperature and without the intervention of a mechanical injury to the cells such as inevitably happens when ice crystals form in the skin. The evidence in question is derived from a number of different sources.

Axon Reflex.—It has been stated already that the skin reacts when cooled to low temperatures. It reacts by producing a local vasodilatation through a local or axon reflex. Now, this reflex is known to be called into play in a large number of other skin reactions: these involve injury of the skin, such as cutting, pricking, burning, freezing, etc., all of which are believed to release histamine-like substance or substances from the skin cells; or the reaction occurs when extracts of skin, or histamine itself, is introduced into the skin. The appearance of a similar vasodilatation on cooling the skin may not be conclusive, but it is suggestive evidence of H-substance release, and to this extent supports the idea of injury (Lewis, 1930).

Local Pain and Tenderness.—Experience would seem to show that in general the production of pain in skin involves damage to the skin. Thus, if heat is applied to skin the earliest evidence of injury, as displayed by vascular reactions, appears at about 42° C. (Lewis and Love, 1926) or very close to the lowest temperature at which the sense of warmth is replaced or supplemented by sense of pain; this temperature is approximately 43° C. (109° F.). Similarly, cold objects give a pure sense of coldness, until as the testing temperature is lowered an element of "sting" or pain is introduced. This new element in the sensory response begins to be detectable very close to the point at which an application of cold to the skin brings the axon reflex response just described—namely, about 15° C. (59° F.).

If a finger is immersed in ice-cold water, pain in it shortly becomes severe enough to be disagreeable, and a finger that has been so treated for a period of, say, ten minutes is subsequently tender and may remain so for many hours (Lewis, 1933). Sometimes in the finger that has been cooled severe burning pain is felt after it has been withdrawn from the ice-cold water; that is so if it is allowed to warm up again too quickly. This pain of recovery can be avoided by re-warming the finger very gradually. The tenderness referred to is unrelated to the pain of re-warming; it appears equally in fingers that are re-warmed slowly and painlessly.

Local Redness.—Two small cubes of ice are laid flat upon the forearms for five minutes; the ice is then removed and both forearms are plunged into water at 30° C. (86° F.), the circulation to one arm being stopped by means of a pneumatic armlet distended on the upper arm. The cooled area on the arm to which the circulation is free becomes red, and this sharply outlined redness disappears gradually in the space of about ten minutes. If now the circulation to the second arm

is released the patch of redness presently becomes defined; this redness disappears in about ten minutes after the circulation is released. Thus the reddening of the cooled forearm is not a direct response of the vessels to cold, for it can persist long after the skin has become warm again. It is due, so it is suggested, to the release of vasodilator substance or substances in the skin as a result of cellular damage; this substance is held *in situ* in the one arm, and its effects begin to decline only when the circulation being restored, the substance begins to be removed (Lewis,* 1930).

Supercooling.—The skin, as will be described later in more detail, can be cooled below its freezing-point without freezing. It occasionally happens that such supercooling is followed by the formation of an acute wheal and flare on the skin (Lewis and Love, 1926). Such a reaction, were it a usual phenomenon, would in itself form conclusive evidence that the normal skin is directly injured by cold; for the reaction typifies the response to injury. But it is not a usual, it is an exceptional, phenomenon, depending on conditions that are still undefined. For that reason no further conclusion can be drawn from this evidence than that in subjects who display this conspicuous reaction cold can directly injure the skin.

Sensitivity to Cold.—A similar limitation applies to evidence derived from those who show extraordinary sensitivity to cold. In these a piece of ice laid on the skin for a minute is followed by conspicuous whealing. These subjects are rare; some of them suffer simultaneously from paroxysmal haemoglobinuria. The sensitivity of these skins to cold can be reproduced in other subjects by infiltrating the skin of the latter with serum from the original patient (Harris, Lewis, and Vaughan, 1929). The cases are remarkable in that whealing may be produced by temperatures as high as 18° C. (64° F.) or even, as in one case recently seen, as high as 25° C. (77° F.). I hesitate to use these two exceptional instances in evidence of the injurious effects of cold upon skins in general, in that they are not sufficiently understood and may be irrelevant; nevertheless, it is necessary here briefly to describe them, for it is also clearly possible that one or both may be no more than exaggerations of normal reactions.

Prolonged Cooling.—In recent observations I have found that if a normal hand or foot is immersed in water at 5° C. (41° F.) for a period of two hours, at the end of this time the reddened member is quite definitely swollen. The skin is less mobile; when thrown into folds these folds are broad; fine crinkling of the skin cannot be produced by manipulating it. The fingers may be swollen enough to prevent complete or easy flexion of the phalanges—either active or passive flexion. The pulps of the fingers are tenser than usual. The backs of the hands may pit perceptibly; sometimes they pit to an extent that makes it clear that not only skin but subcutaneous tissue is involved. This swelling, which may amount to as much as 15% increase of volume, gradually subsides in a few hours. It is not the simple result of imbibition of water by the skin, though some imbibition by the horny layer undoubtedly occurs, for it happens in a hand protected by grease or by the wearing of a loose rubber glove. It can occur recognizably in hands immersed in water for periods of hours at temperatures as high as 10° or 15° C. (50° or 59° F.). This effect is attributed to an injury by cold; presumably the reaction, as is customary in injury, involves the release of H-substance, which in turn acts on the blood vessels. Here it should be stated that histamine (1 c.cm. of 1 in 30,000 base) injected into the skin of the forearm, deep to the skin, is followed by obvious subcutaneous swelling. If several such swellings are made near to each other, distinct pitting of the arm occurs with firm pressure. Thus release of a histamine-like substance would account for swelling both of skin and of subcutaneous tissue.

In the swelling of a hand to cold, as much as 50 c.cm. increase of volume may be found. It is obvious, therefore, that if several of the limbs become cold for a period of hours, as when immersed in sea water or when submitted to other comparable exposure, a very substantial amount of fluid might be lost from the circulation. Perhaps this reaction may account for or con-

tribute to a state of circulatory collapse in wounded or unwounded men exposed to severe cold.

The observations upon human skin here referred to are all such as arise soon after cooling, and are in the nature of acute reactions of the skin; the reactions illustrate the simplest forms of inflammation, characterized by heat, redness, and swelling. There are in addition a number of conditions associated with more prolonged actions of cold and with more prolonged reactions. These will be considered separately in the next lecture.

FAILURE OF IN VITRO TESTS AS A GUIDE TO THE VALUE OF STORED BLOOD

BY

P. L. MOLLISON, M.B., M.R.C.P.

AND

I. MAUREEN YOUNG, B.Sc.

(S.W. London Blood Supply Depot)

Many different solutions are still in use for the preservation of blood during storage. This state of affairs seems to be due mainly to the different criteria that are accepted for the comparison of one solution with another. It will be generally admitted, first, that the value of stored blood, contrasted with that of stored plasma or serum, lies chiefly in its content of erythrocytes, and, secondly, that the real worth of these stored erythrocytes must lie in their ability to survive in the recipient's blood stream after transfusion. Nevertheless, most workers have accepted changes occurring in the erythrocytes *in vitro* as an indication of the value of a given method of preservation—in some cases, at least, assuming that such changes are correlated with *in vivo* survival. The changes most commonly measured are alterations in the osmotic fragility of the erythrocytes and the rate at which spontaneous haemolysis occurs during storage.

Criterion of Positive Value of Preservatives

The power to inhibit haemolysis during storage is certainly a desirable property in any preservative solution, since there are limits to the amount of haemolysed blood that may be safely injected into the blood stream. This, however, is a negative property, correlated with safety but not necessarily with value. The only procedure which seems to us to provide a criterion of the positive value of a given preservative solution is to follow the fate of the transfused erythrocytes in the recipient's blood stream. The *in vivo* survival may be measured by the differential agglutination method originally described by Ashby (1919). In brief, this consists in the transfusion of cells of Group O (IV) to a recipient of Group A (II). After transfusion the recipient's blood contains two types of cells, O and A. The A cells can be "removed" with anti-A serum and the free (O) cells counted. Actually a small fraction of the A cells are not agglutinated, and constitute a "blank" value to be deducted from the total of free cells. By counting the number of donor cells surviving at different intervals of

* Correcting the interpretation of an earlier observation (Lewis and Love, 1926).

time after transfusion, a sufficiently accurate picture may be formed of the survival of the donor cells in the recipient's blood stream.

Using this method, we have tested eighteen different preservatives in a series of over 100 transfusions of stored blood of various ages. In each case the commonly accepted *in vitro* tests were also applied to the blood immediately before transfusion. Data are presented here which emphasize that these *in vitro* qualities are unsound guides to the actual survival of the same erythrocytes when transfused.

In Table I is set out the constitution of three different preservative solutions. In Table II observations on blood stored for varying lengths of time with these solutions are recorded. The *in vitro* properties of the erythrocytes of a given sample and the corresponding *in vivo* survival of the erythrocytes from the same sample are tabulated.

Explanation of Methods and of the Terms used in Table II

On the day of transfusion the stored blood to be tested was carefully removed from the refrigerator. The bulk of the supernatant plasma was siphoned off and the remaining cells from two or more bottles of identical age were pooled.

* DeGowin, Harris, and Plass (1940) have pointed out that Rous and Turner used a different salt of sodium citrate from that in present use. The solution employed by us contains a higher percentage of sodium citrate than the original mixture.

† This is a minor modification of the preservative solution recommended in the Medical Research Council's War Memorandum No. 1.

A sample of this concentrated cell suspension was kept for the performance of *in vitro* tests, and the rest was used for transfusion. Three *in vitro* properties were measured:

1. The Degree of Spontaneous Haemolysis—i.e., the amount of free haemoglobin in the plasma expressed as a percentage of the total haemoglobin content of the sample.

2. The Increase in Haemolysis following a Standard Amount of Shaking in the Presence of Glass Beads.—The figures in Table II express the percentage of haemoglobin (Haldane) found in the plasma after shaking a sample of standard concentration. Previous workers have pointed out that the fragility of erythrocytes to shaking increases during storage, but the relationship of this increasing "mechanical fragility" to subsequent *in vivo* survival of stored erythrocytes has not previously been studied. It is interesting to note that Rous and Turner pointed out in 1916 that there is no constant relation between the mechanical and osmotic fragilities of erythrocytes.

3. Fragility to Hypotonic Saline.—In the table only the mean corpuscular fragility (M.C.F.) is recorded—i.e., the percentage NaCl in which 50% of the cells lyse (Dacie and Vaughan, 1938).

After the preliminary withdrawal of a sample of blood from the recipient the transfusion was begun, and was usually completed in two hours or less. A second venous sample was obtained five to ten minutes after the end of the transfusion. Further samples were taken four to eight hours after the transfusion, at twenty-four hours, and thereafter at suitable intervals.

The number of donor cells found in the first sample after transfusion was taken as 100% survival. Subsequent counts were expressed as percentages of this figure. To take this figure as 100% is, of course, not strictly accurate. If the

transfusion causes an increase in blood volume, and this is subsequently readjusted (i.e., after the collection of the first sample), the number of donor cells will appear to increase. Conversely, if destruction of erythrocytes has already occurred by the time that this sample is taken, to reckon as 100% the figure found makes survival seem better than it really is. From Table II it will be seen that a sample obtained four to eight hours after the transfusion often shows a relative increase of surviving cells compared with the number found immediately after transfusion and that destruction is dominant with the older bloods only. It may

be assumed from this initial relative increase that considerable destruction does not occur during the first few hours after transfusion, except with the older bloods, and the influence of this factor is therefore small.

A further check upon the actual number of donor cells found in the recipient's circulation was made by counting the red cells and measuring the volume of the blood transfused; then, by taking a figure for the recipient's blood volume based on the known height and weight, the expected concentration of donor cells in the recipient's blood stream could be calculated. In this way it could be demonstrated that approximately the expected number of donor cells appeared in the recipient's blood stream.

Results

The findings set out in Table II are representative of the larger number of samples that have been studied. In order to facilitate comparison the *in vitro* qualities of four samples stored with each of these preservatives have been averaged and set against the average *in vivo* survival of the same samples (arbitrarily taken at one month after transfusion) (see Table III). The ages of the samples stored with

TABLE III

Preservatives	In Vitro Tests			Survival In Vivo
	Spontaneous Haemolysis (% Total)	Mechanical Fragility (% Total)	Osmotic Fragility (M.C.F.) (% NaCl)	Percentage Survival at One Month
I. Citrate-Glucose (Rous-Turner) ..	0.5	38	0.74	54
II. Citrate-Glucose (usual) ..	1.5	43	0.61	24
III. Citrate-Sucrose (Wilbrandt) ..	0.6	51	0.34	0

In the above table average figures for *in vitro* findings are compared with *in vivo* survival. For this comparison 4 examples of storage with Preservative I (at 18, 21, 24, and 28 days) have been contrasted with 4 examples with Preservative II (at 18, 19, 23, and 29 days). In the case of Preservative III, with which survival is so much inferior, 3 younger samples (12, 14, and 16 days) were chosen for comparison.

Preservatives I and II are comparable, but in the case of Preservative III younger samples have been chosen because of the much poorer survival. Since the cases are representative of a larger series that has been studied, the following conclusions seem justified:

The survival of transfused cells is better after a given period of storage with Preservative I than with Preservative II and is much less good with Preservative III.

The osmotic fragility of stored erythrocytes is no guide to their subsequent *in vivo* survival. It might appear from this small series that there is even an inverse correlation between osmotic fragility and survival; findings with other preservatives, however, show that there is no constant relation.

A small amount of haemolysis in a given sample does not necessarily imply good *in vivo* survival—e.g., Preservative III.

Fragility to mechanical trauma is only a very approximate guide to survival.

Other Preservatives

Other anticoagulant solutions studied in this way include heparin, sodium citrate with and without glucose in different concentrations and dilutions, "I.H.T.,"* citrate-dextrin, and combinations of sucrose, glucose, and sodium citrate; defibrinated blood was also tested. The findings with these other systems support the contention that fragility to hypotonic saline is no guide, and other commonly measured *in vitro* properties are at best a poor guide, to subsequent survival.

* "I.H.T." is the name given to an anticoagulant solution containing 0.5% sodium citrate, 0.7% NaCl, and traces of other salts; this solution has been much used in Russia (Bagdassarov, 1937).

On the basis of *in vivo* survival tests the preservative solutions used fall into two main groups: (1) systems containing no glucose; (2) systems containing glucose.

1. The first group includes heparinized blood, defibrinated blood, blood stored with "I.H.T.," with sodium citrate, and with citrate-sucrose and citrate-dextrin mixtures. After the transfusion of blood previously stored with any of these anticoagulant solutions for less than seven days the erythrocytes are found to survive extremely well—i.e., virtually as well as those of fresh blood. (After a fresh-blood transfusion it is found that the donor cells are slowly and steadily eliminated over a period of approximately 100 days—i.e., about one-third are eliminated during each month after transfusion (Ashby, 1919; Martinet, 1938).) Subsequently deterioration is rapid; and after two weeks' storage the majority of the transfused cells are usually eliminated from the recipient's circulation within twenty-four hours of the transfusion. To particularize, blood stored with a large relative volume of 3% sodium citrate falls below the average for this group, whereas blood stored with dextrin survives a little better than the average.

2. In general, blood stored with glucose survives extremely well after transfusion—i.e., virtually as well as fresh blood—when it has been stored for less than fourteen days. (This is a slightly more conservative estimate than one previously made with a similar type of anticoagulant solution (Mollison and Young, 1940).) There is a progressive deterioration during the third week of storage, but blood stored with glucose for three weeks is usually not completely eliminated from the recipient's circulation for more than a month after transfusion. These remarks apply to citrate-glucose mixtures in which the volume of preservative solution is small compared with the volume of blood (e.g., Preservative II). Survival was not found to be improved by increasing the concentration of glucose in the same relative volume of preservative solution. By adding a relatively greater volume of 5.4% glucose, however, survival is improved, and when the proportions of Preservative I are reached a clear-cut superiority is demonstrable. Thus after three weeks' storage with Preservative I survival is still almost as good as if the erythrocytes were fresh. It might appear from this that dilution is one of the factors responsible for the superiority of the Rous-Turner preservative solution. However, in the absence of large amounts of glucose, dilution was found to have an unfavourable effect upon survival, and it therefore seems that the problem requires further investigation.

The addition of sucrose to various citrate-glucose preservative solutions has a favourable effect upon the osmotic fragility of the stored erythrocytes but does not significantly influence their subsequent *in vivo* survival.

Practical Application of these Results

Owing to the low protein content of plasma obtained from blood stored with Preservative I it is not expected that this type of preservative will come into general use. In any case, the solution has to be modified if it is to be used directly for transfusion, because of the large amount of citrate it contains. DeGowin and Hardin (1940) have reported very satisfactory results from such a modification. Storage of blood with Preservative II gives adequate preservation for two weeks and has the advantage of providing plasma with a protein content of approximately 5 grammes %. This preservative solution is virtually the same as that at present in use at the Medical Research Council's Blood Supply Depots, and, as has been mentioned above, it does not seem to be improved by increasing the concentration of glucose.

It may be well to call attention to a few instances from the literature in which fallacious conclusions have been

This reversal of changes in osmotic fragility may also be studied *in vitro*. For instance, in the case referred to above a sample of the donor cells was placed in fresh compatible plasma for one hour and its osmotic fragility was then re-estimated. It was found that the M.C.F. of the cells had practically reverted to normal (actually 0.45% NaCl). This effect was found to be constant with this particular preservative. It should be pointed out that although the majority of the cells in a given sample succeed in re-acquiring an approximately normal resistance to hypotonic saline, a few may rupture. The most likely explanation of this reversal in osmotic fragility is that glucose is washed out of the cells when they are placed in a solution of relatively high tonicity at room temperature.

Reversal of osmotic fragility was also observed when blood stored in a solution of glucose was re-suspended with blood stored in a solution of glucose.

Reversal of osmotic fragility was not found to occur with blood stored in certain other preservatives. For instance, when erythrocytes that had been stored with Preservative III were placed in fresh plasma their mean corpuscular fragility did not appear to be affected. This is probably because alterations in the base content of the erythrocytes have occurred and because base is not so mobile as glucose. Nevertheless, the fact that the M.C.F. of stored erythrocytes can be altered in certain circumstances by allowing them to stand in fresh plasma is a further reason for regarding the osmotic fragility, as usually measured, as being an artificial criterion of value.

Summary

Summary

The *in vivo* survival of the erythrocytes of stored blood following transfusion cannot be predicted from a knowledge of the results of the commonly accepted *in vitro* tests made upon the sample. The results of work based upon such *in vitro* tests may therefore be completely fallacious.

Many different preservative solutions have been used to study their effect on the survival of erythrocytes.

Many different preservative solutions have been tested for their effect on the *in vivo* survival of the subsequently transfused erythrocytes. Some details of results obtained with three of these solutions are given and results with the rest are summarized.

We should like to thank Dr. J. F. Loutit, director of this depot, for facilitating these investigations. We also wish to thank Dr. M. Maizels for helpful criticism.

The American Film Centre, 45, Rockefeller Plaza, New York City, has established a section on films in health education and medicine under the charge of Dr. Adolf Nichtenhauser. The new section will be a clearing-house and information centre on the use and production of technical films of this character. From it the centre will evaluate existing health films in collaboration with health experts and publish lists of recommended films. Attention will also be paid to the technical medical film, especially with regard to its use in medical schools. The American Film Centre is an educational organization established three years ago and supported by the Rockefeller Foundation, which has now made a three-year grant towards the Section on Health and Medical Films.

The *in vivo* survival test showed that the recipient's blood stream contained approximately 560,000 donor cells per c.mm. (the expected number) immediately after the trans-

"WOUND PHAGEDAENA"**REPORT OF TWO CASES**

BY

ALEXANDER CALLAM, D.Sc., M.D., F.R.C.S.Ed.*Honorary Surgeon, Victoria Hospital, Burnley*

AND

ALEXANDER DUFF, M.D., F.R.C.S.Ed.*Resident Surgical Officer, Municipal General Hospital, Burnley*

The term "phagedaena" suggests to the modern student of surgery a sloughing condition of the male external genitalia arising in connexion with a venereal infection and caused by anaerobic organisms. For many past generations of surgeons, however, it had a much wider application, and was one of the varieties of "hospital gangrene"—that dreaded miscellany of septic infections now happily almost unknown. For the reasons stated later we consider that the following two cases may be fitly described under this title.

Case Reports

Case 1.—A man aged 46 had appendicectomy performed (A. C.) for acute appendicitis on December 8, 1939. His illness was of seven days' duration and the appendix was perforated, so that it was considered advisable to drain both the abdomen and the wound. The wound discharged, but the temperature remained normal until the eleventh day, when a rapidly spreading inflammation of the edges became apparent. The temperature became irregular (about 101°) and later intermittent with a maximum of 100°, and there was pain in the wound region. By the eighteenth day three-quarters of the area of the abdomen was involved, the skin and subcutaneous tissue having disappeared entirely, leaving the muscle exposed. A further area around was swollen and purple, and discharged pus at many separate points: this area was very tender. Pus taken from the wound on the eighteenth day was examined (Dr. A. Beck) and showed streptococci, Gram-positive diplococci, and *B. proteus*. The streptococci were non-haemolytic, and grew both aerobically and anaerobically. In view of this report and of Meleney's work, dressing with a zinc peroxide cream was tried, but the condition spread very rapidly and the patient died on the twenty-first day after operation.

Case 2.—A man aged 54 had had an empyema operation in 1933, and discharge from the scar had recurred annually ever since. Two weeks before admission he had had incision and drainage at another hospital; the wound was still discharging. On examination on September 7, 1939, two soundly healed scars were seen over the left posterior axillary line. A little further back there was a granulating area about two inches in diameter and apparently healthy; still further back was a small ulcerated area with sloughing edges. X-ray examination (Dr. J. Grieve) showed neither residual empyema nor sequestra in the resected rib. There was no evidence of gas in the tissues. A tentative diagnosis of post-operative cutaneous gangrene was made. Under a general anaesthetic the edges of the ulcer were excised (A. D.). No trace could be found of any sinus leading into the chest.

After the operation a slow painful inflammatory process with much sloughing continued to spread through the skin and subcutaneous tissues of the back. Treatment with ulseron, and later with sulphamillamide, had no effect; local application of orthoform appeared to lessen the pain, which was severe. In a few weeks the condition had reached the stage shown in the accompanying illustration. The whole of the area originally involved had healed, but the inflammation had spread at the same time in a radiating manner across the back. The appearance was that of an immense carbuncle—patches of purple skin riddled with discharging spots and in places undermined. There was no special tenderness at the edges, but severe pain was felt in the affected area. A moderate secondary anaemia, a leucocyte count of 7,200, and a negative Wassermann reaction were observed.

The pus was examined (Dr. G. A. Cary Lynch) on September 28. Aerobic culture yielded *B. proteus* and other organisms,

but no haemolytic streptococci. Anaerobic culture gave a free growth of non-haemolytic streptococci. On repetition a week later, *B. proteus*, diphtheroid bacilli, and non-haemolytic streptococci were found on aerobic culture, with a feeble growth of streptococci only on anaerobic culture.

Under treatment with zinc peroxide considerable healing resulted, but the inflammatory process was never abolished at all places at once. A serpiginous ulceration continued for months, the patient's condition gradually deteriorating. There were only occasional slight rises of temperature. Copious sputum developed: this was found to contain streptococci and numerous other organisms but no tubercle bacilli. The streptococci were not strictly anaerobic, but grew better aerobically.

By April, 1940, the patient's condition was very low. On account, no doubt, of the long-continued pain and toxæmia, symptoms of confusional insanity appeared, and it was obvious

Photograph of Case 2, showing healed area, area of active ulceration, and surrounding purple area of skin.

that any measure which held out a hope of cure was justified. A very wide excision of the two remaining active areas was carried out (A. D.). Each area was the size of the palm of the hand; all tissue down to muscle was removed, and the excision was carried well beyond the surrounding reddened area of skin. Improvement was very rapid, the mental symptoms disappeared, and the patient was discharged three months later practically healed. He was seen on June 29, 1941, and was then completely healed and back at work. The scar covered the whole left half of the back, was pliable and healthy, and gave him no trouble.

Discussion

Somewhat similar cases have been described by Meleney (1933) under the title of "post-operative progressive bacterial synergistic infective gangrene of skin," by Langston (1938) as "progressive streptococcal ulceration," and by Mitchiner and Cowell (1939) as "spreading subcutaneous or cutaneous gangrene." The last-named authors identify the condition with "hospital gangrene."

Clinical Features.—The articles referred to all give such clear accounts of the clinical features that these need only

be summarized briefly here. The time of onset is from a few days to two weeks after an operation for an infective condition, or the process may arise at any time in connexion with a discharging sinus. The edges of the wound and surrounding area quickly assume the appearance of a large carbuncle. Although suppuration is profuse there is little general reaction. Great tenderness of the inflamed area is usual, unremitting pain is characteristic, and there is severe secondary anaemia.

Course.—The condition may be acute or chronic. Case 1 was so rapidly progressive as to be almost inevitably fatal. Chronic cases are characterized by the slow progress of the lesion and the tendency to heal at one area while spreading at another. Meleney (1935) reports one case of spontaneous healing after twenty-six months. Usually, however, the patient is worn out mentally and physically by pain and toxæmia. Fraser (1919) remarks that in gas gangrene the mind remains acute to the end, in striking contrast to the mental confusion in Case 2.

Prognosis.—There are not enough data to enable us to make an accurate estimate of the mortality, but published accounts leave an impression that it is about 50% whatever treatment is adopted.

Bacteriology.—In our cases non-haemolytic anaerobic streptococci with *B. proteus* were the significant organisms. The streptococci became aerobic later—a tendency noted by Douglas, Fleming, and Colebrook (1920). These workers found that practically all streptococci in infected wounds were anaerobic at first, and emphasize the necessity for anaerobic culture in all such cases. Milian (1930) and Nativelle (1930) found a bacillus of the *proteus* group with streptococci in cases of cutaneous gangrene. They consider that streptococci facilitate the action of the *B. proteus*. Diphtheroid bacilli were reported by Meleney and in our Case 2, while virulent diphtheria bacilli were present in Langston's. Douglas, Fleming, and Colebrook (1920) reported true diphtheria bacilli in 4 of 61 infected wounds, while Fleming (1919) found that they had a powerful stimulating action on streptococci. While, therefore, various organisms and combinations of organisms may be responsible, both our cases were due to an association of non-haemolytic streptococci with *B. proteus*. The diphtheroid bacilli were not an essential part of the infection, being absent in Case 1 and present only in the later stages in Case 2.

Ætiology.—The reasons for the establishment of this particular variety of infective process are obscure. The organisms were probably present in the original infection, and M.R.C. War Memorandum, 1940, No. 2 (p. 2), draws attention to the importance of the presence of necrotic material or foreign bodies in the establishment of anaerobic infections. Cross-infection may be excluded, since the cases were treated by us separately in different hospitals and without any other similar cases occurring in either.

Investigation.—This concerns the surgeon in so far as he provides the bacteriologist with his original material. The recent memorandum recommends the swab, and this was used in the present cases. Since the process spreads centrifugally and not deeply, the advice given to take material from the deepest part scarcely applies. The spreading edge is the most suitable site for obtaining a specimen. The memorandum makes no mention of examination of excised tissue such as was performed by Meleney. It appears to us that such examination might enable the bacteriologist to distinguish between contaminants and organisms actively invading the tissues.

Diagnosis

We consider that these two cases are examples of a well-defined clinical entity whose essential features are: (1) it

arises in connexion with an infected wound; (2) anaerobic streptococci, later becoming aerobic, and *B. proteus*, are present; (3) the lesion spreads through skin and subcutaneous tissues, but not deeper. These considerations enable it to be distinguished from most of the other conditions mentioned by Stewart-Wallace (1935)—namely, common wound infection, erysipelas, ecthyma gangraenousum, specific infections, amoebiasis cutis, and fusospirochaetal infections.

Gas Gangrene.—Although two Medical Research Council reports (1919, No. 39; 1920, No. 57) on anaerobic wound infections were published after the last war, one detailing 65 cases, the condition was not clearly differentiated from gas gangrene. Fraser describes "localized anaerobic infection in wounds" and "slowly spreading anaerobic infections," but regards these as mild varieties of gas gangrene; he does not give a separate description such as would identify them with the present cases.

Progressive Post-operative Gangrene of Skin.—This seems to be the condition most closely allied to our cases. The clinical features of Stewart-Wallace's case—a spreading carbuncular process—were in so many respects like those in our second case as to leave little doubt that these were examples of the same condition. Unfortunately the cultural characteristics of the streptococci in his case were not mentioned. Cox (1936), in a case described under the same title, found a streptococcus that was both aerobic and anaerobic, but states that the lesion was strictly confined to the skin. Langston states emphatically that his case was not one of gangrene, but the organism appears to have produced a lesion in the abdominal walls of guinea-pigs very similar to that in our first case. It appears to us that "post-operative progressive bacterial synergistic gangrene of skin" (Meleney), "spreading subcutaneous or cutaneous gangrene" (Mitchiner and Cowell), and probably "progressive streptococcal ulceration" (Langston) are all conditions essentially similar to those of our patients, and closely allied to one of the varieties of "hospital gangrene." We suggest "wound phagedaena" as a more suitable and concise term than any of the above, including all these conditions and yet excluding the others mentioned in the previous section.

Treatment

Though Meleney and Langston have had success with local application of zinc peroxide, this was unavailing in our cases, as were both uleron and sulphanilamide internally. Incomplete excision is useless, but it is to be noted that the first, evidently incomplete, excision in Case 2 did not accelerate the infective process as it might have been expected to do.

We entirely agree with Stewart-Wallace that there is no doubt at all that the correct treatment is wide excision. Probably with diathermy excision there would be less risk of leaving behind an area of tissue still containing active organisms. In view of the recent activity in research into the chemotherapy of wound infections this opinion may have to be revised soon, but any alternative treatment would have to be well founded in view of the excellent results of a well-planned excision.

Summary

Two cases are reported of a spreading infection of skin and subcutaneous tissues arising from an infected wound or sinus.

The condition appears to be one manifestation of a clinical entity, including "post-operative cutaneous gangrene" and some other similar conditions, closely related to the "phagedaena" of former times.

The infecting agent in each case was an anaerobic streptococcus associated with *B. proteus*.

One case was hopeless from the start; in the other a cure was effected by a wide excision of the lesion.

"Wound phagedaena" is suggested as a suitable name for the condition.

We have to thank our colleagues mentioned in the text for their special examinations and reports: Dr. D. C. Lamont, M.O.H. Burnley, for permission to publish Case 2; and Mr. H. Lawrie, B.Sc., for the clinical photograph.

ENURESIS IN ADOLESCENTS

BY

R. C. BROWNE, B.M., M.R.C.P.*

AND

A. FORD-SMITH, B.M., M.R.C.P.

(From the Nuffield Department of Clinical Medicine,
Oxford)

The Subjects and their Surroundings

The subjects of these observations were boys whose ages ranged from 14 to 20 years. They were members of a farm training colony, some 300 strong, to which they had been sent by the Public Assistance Committees of England and Wales. Most of them had been brought up in institutions, and many of them had been "problem cases." In general the boys were of poor type and intelligence, inclined to lack discipline and to show anti-social traits. Many of them had started life with the adverse bias of illegitimacy, separated parents, or an unkind step-parent. The boys at the colony received training to fit them for farm, gardening, or domestic work or boot-repairing. Positions were found for them in one of these spheres at the completion of their course. They played organized games daily, with swimming in the summer, and went to the pictures once a week, on Saturdays. A few of them had started model aeroplane and fretwork clubs. The colony was run rather along Public School lines, being divided up into several houses, with the usual system of internal government. Everything was done to kindle a feeling of responsibility and public spirit, and much of the government of the colony was in the hands of the boys themselves.

Twenty-one per cent. of them were bed-wetters: this high figure is explained by the fact that the colony is one of the few in England admitting such boys, who thus tend to gravitate there. Most were intractable cases who still wet their beds when admitted to hospital in different and possibly happier surroundings. Occasionally some went home, but the trouble nearly always persisted. It was the custom to segregate the enuretic boys in a separate dormitory with beds equipped with rubber sheets. In an effort to avoid a wet bed later in the night, they were waked two hours after going to bed and made to pass water. Thus it was probable that the conditions tended to encourage

enuresis rather than otherwise, in view of the segregation at night and the constant reminder, in being called, that the worst might happen. Alongside this camp there happened to be a colony of forty Jewish refugee boys of similar ages. They were mostly the sons of Austrian artisans and small shopkeepers. These boys were of good intelligence and physique, and when competing in the sports against the boys in the colony had won all the cups and prizes. Enuresis among them was unknown.

Description of Cases more fully Investigated

Twelve boys from the colony together with one from an external source were admitted to hospital for a more detailed investigation. In addition to careful histories and physical examinations, perianal swabs were taken for threadworms, the lumbar spines were radiographed for spina bifida, and an investigation was made to determine whether the boys passed an abnormal volume of urine by day or night. Intravenous pyelography was performed, and each boy was sent for interview by a psychologist. The method employed to determine whether they passed an abnormal volume of urine consisted, at first, in weighing the bed-clothes before and after sleep. This was found to be not very satisfactory, and eventually a comfortable bag for collecting urine was fitted on before they settled for the night. Ten of the boys had enuresis in hospital.

The average age of the subjects was 17, the youngest being 14 and the oldest 20. Ten of them had unsatisfactory family histories, such as the early death of the parents, a broken home, or a father who suffered from "shell shock." There was a family history of enuresis in only one case. All but one were dull, and even this boy was emotionally immature. This dullness was quite obvious on simple conversational contact, and required no special test for its demonstration. All the boys, except one whose development was retarded, were physically normal. Threadworms were found in three of them. There was no significant chemical or cytological abnormality in their urine, of which they passed a normal volume both by day and by night. Intravenous pyelograms showed normal urinary tracts in every case. Radiographs of the lumbar and sacral spines demonstrated some abnormality in nine out of the thirteen boys. This was frank spina bifida occulta in seven, but a congenital abnormality of the first piece of the sacrum was reported in one, and flattened vertebral bodies in another. The incidence of congenital abnormalities is greater than even the most generous estimates for healthy people.

Common factors in the histories and examinations that were noted, among others, were: (1) an unsatisfactory family history, often with some disruption of the home; (2) poor intelligence; (3) normal physique; and (4) a congenital spinal abnormality.

• Spontaneous Course of the Disorder

A record of the number of wet beds caused by each of three boys was kept for a period of rather more than two years, during which they were untreated. This is shown in Fig. 1. It will be seen that the disease follows an irregular course, being slightly less troublesome in midsummer. In the case of boys C. and M. there was an exacerbation in the early part of 1940 corresponding to the intense cold at that time. Boy W., however, seemed to be unaffected by this. The course of the illness is not unlike that of epilepsy, a similarity which fits in with the low level of intelligence of most of the boys. The frequency of spina bifida occulta further suggests some abnormality in the central nervous system. The demonstration of spontaneous remissions naturally raises the question of any treatment used. If a

spontaneous remission coincides with the administration of a particular drug or treatment, improvement may be wrongly attributed to the latter.

FIG. 1.—Spontaneous course of enuresis in three adolescent boys. The uprights represent the number of nights the boy wetted the bed during each ten-day period.

Effect of Various Drugs

Two groups of six boys sleeping on opposite sides of the same dormitory were investigated. The weekly number of wet beds was collected and expressed as a percentage of the total possible number, assuming each boy had wet his bed every night. The two groups were studied continuously for a year. At night before going to bed each group was given a drug alternately, the other having inert control tablets similar in size, shape, and colour. At the end of the week the conditions were reversed. Occasionally no drugs or control tablets were given either group of boys. One of the masters or prefects at the colony gave the drugs. Once when it was suspected that they were not being administered, methylene-blue tablets were given, and a random boy chosen who urinated in our presence. The colour of his urine showed that the suspicion had been groundless. The drugs were given in doses which are the maximum or above the maximum of those in common use (see Table).

Fig. 2 shows the number of wet beds throughout the experimental time, for both treated and control groups; the mean weekly temperature is included in the graph. Just

as with the three individual boys, it seems as if the disease runs an irregularly rhythmic course with no apparent relation to drug therapy, and is only slightly affected by the temperature of the weather at the time. The number of wet beds in both groups was nearly equal, the control group having 45% of the total possible, and the group receiving supposedly active drugs 46%. None of the drugs given had

Table showing Effect of Drugs upon a Group of Six Enuretic Boys

Drug	Dosage in Grammes	Better	Worse	Weeks Administered, Inclusive
		Weeks	Weeks	
Trasentin (Ciba)	0.075-0.225	3	3	2nd to 7th
Ephed. sulph.	0.06-0.24	3	2	8th to 12th
Ext. bellad. sicc.	0.06-0.24	2	2	13th to 18th
Ext. bellad. sicc. 0.06 gm. and ephed. hydrochlor. 0.06 gm.	1-4 tablets	2	1	19th to 21st
Phedracin (Ciba)	0.4-0.6	0	3	22nd to 24th
Methylatropin. nit. (eumydria, Bayer)	0.003-0.005	2	1	26th to 28th
Phystog. salicyl.	0.0013-0.0026	1	1	29th and 30th
Theophyll. mono-ethanolamin. (theamin, Lilly)	0.2-0.4	3	1	31st and 32nd, and 34th and 35th
Mersalyl 0.08 gm. and theophyll. 0.04 gm.	2 tablets	1	1	36th and 37th
Methylthionin. chlor.	0.3	1	1	38th and 39th
Barbitone soluble	0.6	1	1	40th and 41st
Sod. diphenhydantoin (solan-toin, Glaxo)	0.2	2	1	42nd to 44th

a definite action on the enuresis. This was most strikingly shown in the case of belladonna, in spite of its reputation in this disease; for when the drug was given in the massive dose of 4 grains the treated group became worse whereas the control group improved. During that week one of the treated boys showed symptoms of atropinism and became manic. The table shows these results and indicates the weeks in which each drug was given. In addition to the drugs mentioned in the table, amitil (Lilly), prominal (Bayer), pseudo-ephedrine (Burroughs Wellcome), and torantil (Bayer) were also tried without success.

Two diuretics were administered—theamin, a xanthine derivative, and mersalyl, an organic mercury compound combined with a xanthine derivative. The absurd result was obtained that improvement occurred in three out of four weeks when mersalyl was given, deterioration taking place during the other week.

FIG. 2.—Frequency of enuresis in treated and untreated subjects. The boys given drugs wetted the bed just as often as the controls. There was no close correlation between frequency of enuresis and mean temperature.

Summary

Enuresis in a group of adolescents in a farm training colony was usually accompanied by unfortunate home conditions, poor intelligence, a normal physique, and a high incidence of occult spinal deformities.

The disease followed a rhythmic but irregular course; it was more frequent in cold weather, but the correlation was not close.

In a controlled therapeutic experiment on a group of twelve boys a series of drugs, including belladonna and ephedrine, was tried. None had any effect on the enuresis.
